The narcotic antagonist naltrexone can block the euphoriant effects of heroin and other opiates, prevent the development of physical dependence, and afford protection from opioid OD deaths. Although naloxone is pharmacologically similar to naltrexone, it is impractical to use because of its short duration of action and its extremely poor oral bioavailability. Naltrexone is orally active and provides a dose-related duration of opioid blockade. An oral dose of naltrexone 100 mg will block opiate effects for 2 days, and 150 mg for 3 days. Thus, dosing on Monday, Wednesday, and Friday is possible; however, it is recommended to use 50 mg every morning (qam) because it is easier to remember for the patient and will result in better adherence. Naltrexone is also available as an injectable extended-release formulation for once-monthly use.[39] Patients selected for naltrexone therapy must be opioid free to avoid precipitation of withdrawal. For heroin- or morphine-dependent patients, a 4- to 7-day wait period is recommended, whereas longer half-life opiates can require a 10- to 14-day wait. Patients who are highly motivated to abstain have been most successfully treated with this drug.

Because A.X. has had a short duration of opiate misuse, he is a good candidate for outpatient buprenorphine/naloxone or naltrexone. Methadone is equally effective, but does require enrollment into a clinic, which may or may not be practical for him. Methadone clinics are considered more effective than are the other choices because the addiction becomes more severe.

Research suggests that physicians consume more opioids, sedatives, and alcohol than do the general public, but less tobacco.[40] The risk is largely based on access to drugs of abuse, and drug dependence is described as an occupational hazard for health care providers. Fentanyl (injectable as well as transdermal formulations) and meperidine are primarily, but not exclusively, drugs of abuse

among health care providers. Hospice workers and veterinarians also have access to high-potency opioids. Studies have noted that substance use was highest in psychiatrists and emergency medicine physicians and lowest in surgeons and pediatricians.[40] Fentanyl is associated with rapid development of dependence, intense tolerance, and drug-seeking behavior in addicted physicians for a period of months rather than years.

A comprehensive assessment of addicted health care providers is necessary to determine whether professional impairment is present, and whether issues involving public health and safety or violations of ethical standards, such as professional boundary violations or improprieties, require that the heath care provider be reported to his or her respective medical board. A physician's registration with the federal DEA may need to be suspended. It generally is accepted that health care providers require longer durations of treatment because they are held to a higher standard of recovery owing to concerns of public safety, and because they may be clever at concealing their illness.[40]

Health care providers are often good candidates for naltrexone therapy (particularly the long-action injection) because of the need to remain drug free despite continued access to opioids at work.

Opiate Use Disorder Treatment in Pregnancy

CASE 90-5

Question 1: J.R., a 28-year-old female, has been maintained on 100 mg of methadone daily for the past year. J.R.'s last menstrual period was 8 weeks ago, and she took a home pregnancy test yesterday, which was positive.

What is the recommended treatment for pregnant patients?

Methadone has been accepted since the late 1970s to treat opioid use disorder during pregnancy.[20] Methadone maintenance was determined to be the standard of care for pregnant females with opioid use disorder by a 1998 National Institutes of Health (NIH)

consensus panel.[41] Currently, methadone is the only opioid medication approved by the FDA for medication-assisted treatment of opioid use disorder in pregnant patients. Females maintained on methadone frequently have regular menstrual periods, ovulate, conceive, and have normal pregnancies. Heroin-addicted mothers, however, generally experience more complicated pregnancies because their lifestyles often predispose them to a poor general state of health and precludes adequate prenatal medical care.[22] Infants born to heroin-addicted mothers may also be exposed to other substances (eg, alcohol, cocaine, and tobacco). These infants tend to be smaller, weigh less at birth, and are often born prematurely compared with the children of females not using opiates.[22]

WITHDRAWAL DURING PREGNANCY

J.R. should continue methadone maintenance to avoid precipitating a withdrawal syndrome or a relapse to opiate addiction. Both relapse and withdrawal syndrome could lead to spontaneous abortion.[20] A structured methadone maintenance program provides access to counseling and perinatal medical care, which are additional benefits. The dose of methadone should be titrated individually throughout the pregnancy, and may even need to be increased and switched from on prescription (QD) to twice-daily (bid) dosing because of changes in kinetics that occur during pregnancy.[2] The neonate can be managed for either opioid-induced CNS depression or methadone withdrawal after delivery, as needed.

Methadone continues to be the standard of care for the management of opioid dependence in pregnancy; however, a growing body of evidence suggests buprenorphine may be a reasonably safe alternative.[15] Also, most evidence suggests that infants born to buprenorphine-maintained females have a lower incidence of neonatal abstinence syndrome (NAS) and shorter hospital stays.[42–44]

NEONATAL ABSTINENCE SYNDROME

Case 90-5, Question 2: Because methadone crosses the placental barrier, will J.R.'s infant exhibit opioid withdrawal symptoms after birth, and, if so, how should they be managed?

Methadone crosses the placental barrier and can cause CNS and respiratory depression as well as opioid withdrawal in the newborn. Higher doses of methadone are correlated with increased severity of NAS and longer duration of treatment needed for infants affected.[45] In general, the most common opioid NAS symptoms include restlessness, tremors, a high-pitched cry, hypertonicity, increased reflexes, regurgitation, tachypnea, diarrhea, and sneezing. Seizures are associated with, but not necessarily caused directly by, opioid withdrawal in the neonate.[46]

Management of the neonate's opioid withdrawal syndrome entails careful attention to hydration, with demand feeding and symptomatic care. Treatment of opioid NAS should begin when symptoms occur; prophylactic therapy is not recommended. Mild withdrawal symptoms generally do not need therapy, but moderate-to-severe symptoms may require ≥14 days of treatment.[46]

Symptoms of physiologic withdrawal are usually apparent within 48 hours of birth. Treatment can be initiated at this time. Currently, NAS is treated with morphine.[42,46–49] Morphine can be started at a dose of 50 µg/kg given orally four times daily and titrated to control symptoms. Once the NAS symptoms have stabilized, the dose can be decreased daily by 20% until discontinuation of the drug. Phenobarbital is preferred for the treatment of NAS in cases of combined dependence or benzodiazepine dependence or if maximum doses of opiate have been used.[42] If used, phenobarbital is instituted in doses of 5 to 10 mg/kg/day in the first 24 hours, then tapered symptomatically, usually about 20% per day.

If J.R.'s infant displays opioid withdrawal symptoms (eg, feeds poorly, becomes tremulous or agitated), morphine at a dosage of 50 µg/kg orally given four times daily would be an appropriate intervention. This dosage is given until symptoms stabilize and then gradually tapered (eg, 20% each day) during the next week.

Buprenorphine has also shown positive data supporting its use and is a potential option if morphine is unacceptable.[46]

BREAST-FEEDING

Methadone is excreted into the breast milk of methadone-maintained mothers. The amount of methadone in the breast milk is unlikely, however, to have adverse effects on the infant.[50] Furthermore, studies have found minimal transfer of methadone into breast milk.[20] There is little data regarding the safety of buprenorphine in breast-feeding. One study found low levels of buprenorphine and its active metabolite, nalbuphine, in infants' urine.[51] Breast milk offers advantages clearly beneficial to infants, and J.R. should be encouraged to breastfeed her infant.

SEDATIVE-HYPNOTICS (NON-ETHANOL ALCOHOL)

The sedative-hypnotics are a diverse group of compounds with broad clinical uses, including anesthesia, treatment of anxiety, and treatment of insomnia. Ethanol, also a sedative-hypnotic agent, continues to be the most widely abused substance in the United States, and is discussed later. Benzodiazepines have become the prototypical sedative-hypnotic drugs of abuse. Other abused sedative-hypnotic drugs include carisoprodol and γ-hydroxybutyric acid (GHB). Carisoprodol, a nonscheduled skeletal muscle relaxant, has an active metabolite meprobamate, a sedative-hypnotic agent with known abuse potential.[52] GHB is a putative neurotransmitter abused for its euphoric and sedative-hypnotic effects. Although sedative-hypnotics can be abused as monotherapy, they are more commonly used as adjuncts to other chemicals such as opiates and ethanol alcohol (EtOH).

Abstinence Syndromes Associated With Sedative-Hypnotic Dependence

CASE 90-6

QUESTION 1: During a year of therapy for anxiety, B.J. increased his dose of alprazolam to two 1-mg tablets five times a day. He has admitted to "doctor shopping" and buying alprazolam on the street. He states he uses the benzodiazepine to get high, but he also becomes extremely anxious if he does not use any alprazolam for more than an afternoon.

Will he experience withdrawal symptoms if he suddenly discontinues alprazolam?

Patients who have been on long-term courses of therapeutic doses of sedative-hypnotics often experience withdrawal symptoms on abrupt discontinuation of therapy. Withdrawal syndromes seen with sedative-hypnotics are similar to those seen with alcohol withdrawal and can include insomnia; anxiety; tremors; headaches; restlessness; nausea; vomiting; hypertension; tachycardia; hypersensitivity to light, sound, and touch; and perceptual distortions.[53] Generalized tonic–clonic seizures can occur as isolated seizures or as status epilepticus. The psychoses that develop resemble the delirium tremens produced by alcohol withdrawal, and are usually characterized by disorientation, agitation, delusions, and hallucinations. During the delirium, hyperthermia and agitation can lead to exhaustion, rhabdomyolysis, cardiovascular collapse, and death. Abstinence from short-acting barbiturates and meprobamate produces symptoms that peak within 1 to 5 days. Discontinuation of short-acting benzodiazepines (eg, lorazepam, oxazepam, alprazolam, and temazepam) results in the abrupt onset of withdrawal symptoms, usually within 12 to 24 hours of the last dose. Long-acting agents, and those with active metabolites, have a gradual onset of milder withdrawal symptoms compared with the short-acting agents. Withdrawal symptoms after chronic use of long-acting benzodiazepines typically occur within 5 days of cessation and peak at 1 to 9 days after the last dose. Severity of these

symptoms can also be affected by factors such as personality traits, baseline anxiety, and level of education.[53]

B.J. has been abusing alprazolam, taking more than the recommended maximal dose. Likely, he will experience withdrawal, possibly including seizures, if he were to abruptly discontinue the alprazolam. His withdrawal from this medication should be medically managed.

Treatment of Sedative Withdrawal

Three general medication strategies are used for withdrawing patients from sedative-hypnotics: tapering; substituting (and gradual taper) of phenobarbital for the drug of dependence; and substituting (and gradual taper) of a long-acting benzodiazepine for the drug of dependence.[54] Gradual tapering of the drug of dependence is appropriate for patients with therapeutic dose dependence or those taking long-acting sedative-hypnotics, who are not currently abusing alcohol or other substances. A recent meta-analysis suggests that benzodiazepine monodependence management by gradual taper is preferable to abrupt discontinuation.[55] The patient who is abusing sedative-hypnotics already has a strong association between the drug of choice and certain desired effects. Therefore, to minimize exacerbating addictive disease, substitution and taper with a long-acting therapeutic agent is preferred.

The phenobarbital method is used in some drug treatment programs. The pharmacologic rationale for phenobarbital substitution is that it is long acting, producing little changes in serum levels between doses, thereby preventing breakthrough withdrawal symptoms. Lethal doses are many times higher than are toxic doses, and dysphoria occurs with elevated dose, rendering it less desirable for abusers.

The standard method involves calculating a phenobarbital replacement dose for the total daily dose of the sedative-hypnotic being abused. The calculation is based on phenobarbital equivalents (**Table 90-3**). If multiple sedative-hypnotics are being used, the totals

for each drug and alcohol (amount of pure ethanol) are summated. The total phenobarbital substitution dose should be given in divided doses, three or four times daily (to avoid dysphoria). Because the calculated dosage is an estimate based on patient history and may be inaccurate, it is advisable to administer a test dose if the calculated replacement dose is >180 mg/day. The test dose, generally one-third the total dose, is given to the patient, who is then observed for 1 to 2 hours. The patient is observed for mitigation of withdrawal symptoms and signs of overmedication, such as somnolence or incoordination. Once an appropriate dose is determined, the patient is usually stabilized on that dose for 1 to 2 weeks. After stabilization, a gradual taper of phenobarbital is instituted, with dosages reduced by 15 mg weekly or every other week, or 10% of the current (starting) dose per week. For the last 25% to 35% of the taper, the rate is slowed to keep the patient stabilized. The taper should be held for a few days if withdrawal symptoms occur.[53]

Table 90-3

Hypnotic Dose Equivalent to 30-mg Phenobarbital

Pure ethanol 30–60 mL	Clonazepam 1–2 mg	Pentobarbital 100 mg
Alprazolam 0.5–1 mg	Diazepam 10 mg	Secobarbital 100 mg
Butalbital 100 mg	Flunitrazepam 1–2 mg[a]	Temazepam 15 mg
Carisoprodol 700 mg	Lorazepam 2 mg	Triazolam 0.25–0.5 mg
Chlordiazepoxide 25 mg	Oxazepam 10–15 mg	Zolpidem 5 mg

[a]Not approved for use in the United States.

B.J. has a substance use disorder to alprazolam. Tapering of alprazolam or conversion to phenobarbital will both result in a safe withdrawal. His total dose of alprazolam is 10 mg/day, so if phenobarbital is used, he should receive 300 mg divided three or

four times a day. The total daily phenobarbital dose or alprazolam dose should be tapered by 10% of the dose per week as tolerated.

γ-Hydroxybutyric Acid

GHB, commonly referred to as *liquid ecstasy*, is a potent "club drug." Once available as an over-the-counter nutritional supplement, primarily used by bodybuilders for its muscle building effect, the FDA removed it from the retail market in 1990 because of widespread reports of poisoning. In 2000, it was classified as a Schedule I drug; however, a GHB-containing product, sodium oxybate, is available as a Schedule III prescription drug for the treatment of cataplexy associated with narcolepsy.[56] GHB is found in mammalian brain tissue, where it is derived from conversion of its parent neurotransmitter, γ-aminobutyric acid (GABA).[57] It is believed to be a neurotransmitter. Experimental evidence suggests that the mechanism of action of exogenously administered GHB involves agonist activity at the $GABA_B$ receptor.[58]

GHB has CNS depressant effects, and is abused for its euphorigenic properties, disinhibition, and enhanced sensuality. Its psychic effects are similar to those of alcohol, and include increased libido, short-term anterograde amnesia, and a dreamy, altered sensorium. It has a steep dose–response curve, and common adverse effects include dizziness, nausea, weakness, agitation, hallucinations, seizures, respiratory depression, and coma. Its effects are synergistic with alcohol. GHB OD may be fatal, and there is no antidote. Treatment for GHB OD is primarily supportive.[59]

Highly addictive, tolerance and physical dependence can occur with regular use of GHB, and a withdrawal syndrome has been seen in people who have taken high doses of it (~18 g/day or more, although doses are variable in solution form) with frequent dosing (every 1–3 hours).[60] Withdrawal symptoms can include muscle cramps, nausea, vomiting, tremor, anxiety, insomnia, tachycardia, restlessness, and delirium or frank psychosis. Death caused by pulmonary edema has been reported. Treatment of withdrawal

involves supportive care, including use of benzodiazepines (eg, lorazepam or diazepam) for sedation. Vital signs need to be monitored, and the patient's airway should be kept clear in case of emesis. Withdrawal can last up to 2 weeks.[60]

Misrepresented sometimes as a natural and safe hypnotic, the low therapeutic index, and the unknown purity of illicit supplies, particularly when sold in solution, make GHB a potentially dangerous drug. Physical dependency is a possibility as well. GHB, along with the benzodiazepine flunitrazepam, are considered "date rape" drugs because they cause profound hypnosis and amnesia. This is intensified when mixed with alcohol, which is often how the sexual predator gives it to his victim.[56]

CENTRAL NERVOUS SYSTEM STIMULANTS

Cocaine

Cocaine is a naturally occurring alkaloid derived from the *Erythroxylon coca* plant, found mainly in the Andes Mountains of South America. Cocaine was first isolated in the 1800s and was a common ingredient in tonics and elixirs of the 1900s. The Harrison Narcotic Act of 1914 prohibited nonmedical use, and in 1970 it became a Schedule II controlled substance. According to the 2018 National Survey on Drug Use and Health, nearly 1 million people in the continental United States have a diagnosed cocaine use disorder within the past year, which is similar to the rate in 2017.[4] Cocaine is a CNS stimulant and has vasoconstrictive and local anesthetic properties. Cocaine's stimulant effects are primarily caused by blockade of the neuronal reuptake of dopamine (DA) and norepinephrine, with a small effect on serotonin. It also facilitates the neuronal release of DA and norepinephrine. This results in an overall increase in availability of these neurotransmitters in the synaptic space. Cocaine also has other indirect effects on neurophysiology, including effects on the endogenous opioid systems.[61,62] Cocaine is

associated with compulsive use. The powerful reinforcing effects of cocaine have been identified as occurring in brain regions rich in dopaminergic nerve terminals.

DOSAGE FORMS AND ROUTES OF ADMINISTRATION

In the manufacture of cocaine, organic solvents are used to solubilize the alkaloidal bases from the leaves, which are then precipitated to form a sticky material, called “pasta” or “cocaine paste.” The benzoylmethylecgonine (cocaine) in this “pasta” is separated from most of the other plant alkaloids, converted to hydrochloride or other salts, precipitated, and dried. This product is the white cocaine hydrochloride powder usually seen in the illicit market. The final product is usually “stepped on” or “cut” (diluted) with various adulterants to increase profits for the dealers. According to the DEA, the average purity of cocaine in 2017 was 64.3%, which is higher than that in previous years.[6] Powdered cocaine is generally snorted. Usually 10 to 25 mg of powdered cocaine is placed on a mirror or flat surface, formed into a line, and then insufflated through a straw or rolled dollar bill. A typical low-to-moderate user may consume 1 to 3 g/week. Cocaine powder can also be used for IV injection. The highly water-soluble powder is usually mixed with water and injected. When cocaine is injected simultaneously with heroin, this is known as a “speedball.”

Cocaine hydrochloride melts at a high temperature, destroying much of its psychoactivity in the process. Therefore, it is inefficient to smoke cocaine hydrochloride in this form. The use of “freebase” cocaine became popular during the late 1970s because this form of cocaine has a lower melting point and can therefore be smoked, producing an intense rush. For freebase, the cocaine hydrochloride is dissolved into ethyl ether. The synthesis of freebase is dangerous, and the resultant product may contain residual organic solvents, thus making it highly volatile and putting the user at risk for burns.

In the mid-1980s, a safer and easier method for extracting the cocaine base supplanted the traditional freebase process. In the manufacture of “crack,” cocaine hydrochloride is dissolved in water.

When alkali (bleach or sodium bicarbonate) is added to this aqueous solution, the free alkaloidal base ("crack") precipitates out, whereas the salts and some adulterants stay in aqueous solution. The precipitate is commonly referred to as a *rock*. The size of the rock varies, but generally ranges from one-tenth of a gram to a half a gram.

PHARMACOKINETICS AND EFFECTS

Cocaine generally produces a euphoriant action with a rapid onset and short duration. Snorting cocaine generally produces euphoria and stimulation within 2 minutes; smoking produces these effects within 6 to 8 seconds. Cocaine has a short elimination half-life of ~30 minutes owing to its rapid metabolism by esterases in the plasma, liver, brain, and other tissues.[62] When alcohol and cocaine are consumed together, a metabolite, cocaethylene, is formed. With a half-life three to five times longer than that of cocaine, cocaethylene intensifies both the euphoric and the toxic effects of cocaine.[63] The risk of death from cocaine consumed with alcohol is 18 to 25 times greater than that with cocaine alone.[63]

An initial relaxed, euphoric, gregarious, talkative, hyperactive state characterizes the "high" of cocaine. In addition, the person may report increased interest in sexual matters, diminished short-term memory, periods of intense concentration on one limited subject, diminished hunger, hypervigilance, and a peculiar, slightly out-of-body sense of one's actions. Without additional doses of cocaine, these feelings usually resolve into a state of mild depression, fatigue, hunger, and sleepiness by 1 to 3 hours. Physiologic manifestations include mydriasis, sinus tachycardia, vasoconstriction with hypertension, bruxism, repetitive behavior, hyperthermia, and talkativeness. After a few hours, continuous self-administration of cocaine will begin to progress from euphoria to dysphoria, to hallucinosis, and then to psychosis. Some users engage in nonstop binges of self-administration until psychological toxicity develops.[64]

ADVERSE EFFECTS

In 2011, there were reports of 505,224 cocaine-related visits to an emergency department (ED) in the United States.[65] The potential adverse effects associated with both acute and chronic use of cocaine are numerous and involve most organ systems in the body.

The cardiac complications associated with cocaine use include hypertension, arrhythmias, myocardial ischemia and infarction, dilated and hypertrophic cardiomyopathy, myocarditis, aortic dissection, and acceleration of atherosclerosis. These cardiac effects have occurred in individuals with and without underlying heart disease who have taken large or small doses by all routes of administration and may be associated with acute or chronic use. The cardiac events can occur before, during, or after other toxicities, such as seizures, and can be fatal. The mechanism of cocaine-induced myocardial infarction (MI) is most likely multifactorial, involving one or more of the following processes: coronary artery vasoconstriction, increased myocardial oxygen demand related to increased blood pressure and increased heart rate, increased platelet aggregation and thrombus formation, coronary vasospasm, and arrhythmia. The risk is greatest within the first hour of use.[66] In patients presenting to the emergency room with acute chest pain, a significant association between cocaine use and acute coronary syndromes has been established based on data from the emergency department.[67]

The MM of acute coronary syndromes differs when cocaine is the cause. Specifically, nonselective β-blocker therapy (ie, propranolol) is contraindicated because of unopposed α-effects, thrombolytics should be used with caution, and nitroglycerine and benzodiazepines are part of first-line therapy.[63,64,68] In patients with cocaine-associated chest pain, a 12-hour observation period to rule out MI or ischemia is probably sufficient before discharge from a medical facility.[64]

Cocaine has also been associated with cerebrovascular catastrophes. Stroke can occur as a result of increased blood pressure, vasoconstriction, or thrombosis. Seizures are another CNS complication. Seizures can occur with first use and are most often single, generalized tonic–clonic seizures. Most occur within 90 minutes of drug use, when drug plasma concentrations are highest.[62]

The route of cocaine administration also affects the nature of the adverse effects. For example, pulmonary complications, including pneumomediastinum, pneumothorax, pneumopericardium, acute exacerbation of asthma, diffuse alveolar hemorrhage, pulmonary edema, and "crack lung," are associated with smoking crack cocaine. Crack lung is a syndrome of acute pulmonary infiltrates associated with a spectrum of clinical and histologic findings.[63] Snorting cocaine can lead to perforation of the nasal septum because of the drug's local anesthetic and vasoconstrictive effects. IV use of cocaine has been associated with renal infarction, wound botulism, viral hepatitis, HIV infection, bacterial endocarditis, sepsis, and other infectious complications.

COCAINE USE DISORDER

A person who uses cocaine despite adverse consequences (ED visit), uses it compulsively, suffers withdrawal symptoms, and alleviates symptoms with further use is diagnosed with cocaine use disorder per the *DSM-5*. According to the National Survey on Drug Use and Health for 2018, ~ 977,000 people 12 years or older suffered from cocaine use disorder in the previous year.[4] Prolonged or heavy use of cocaine has been associated with the development of tolerance to some of its central effects. Tolerance is caused by adaptive changes in the brain.[62,69] A withdrawal syndrome may follow long-term or binge use. The initial, acute symptoms, referred to as the *crash*, consist of depression, fatigue, craving, hypersomnolence, and anxiety. Anhedonia and hyperphagia soon follow. Although most symptoms are mild and resolve within 1 to 2 weeks, the dysphoria and anhedonia can persist for weeks. These symptoms do not produce profound physiologic changes and are generally not life-threatening.[64]

TREATMENT OF COCAINE USE DISORDER

Most cases of simple cocaine withdrawal do not require medical treatment. However, multiple pharmacologic therapies to facilitate abstinence from cocaine have been, and continue to be, under

investigation. Because cocaine affects multiple neurotransmitters in the brain, effective drugs need to target more than one molecule.[70] Most studies have yielded variable results, and to date no drug that is proved effective in treating cocaine dependence exists.[15] Studies of DA agonists (amantadine, selegiline, levodopa/carbidopa, and pergolide), antidepressants (desipramine, fluoxetine, and bupropion), and carbamazepine have yielded inconsistent findings. The long-acting amphetamines (dextroamphetamine and methamphetamine) have shown promising results, although high dropout rates have been reported in clinical trials.[71,72] Methylphenidate has been investigated as "maintenance treatment" to satisfy the cocaine addict's desire for further enhancement of mood; however, methylphenidate also can stimulate a powerful craving for the more intense euphoria of cocaine and has significant abuse potential. Topiramate, baclofen, tiagabine, and modafinil have also shown promising results.[70] A cocaine vaccine is currently under investigation.[73] Psychosocial treatments focusing on abstinence have been effective in the treatment of cocaine dependence.[70] CBTs and behavioral therapies, such as contingency management, along with 12-step–oriented individual counseling can be useful, although the efficacy of these therapies varies. Participation in a 12-step self-help group (Alcoholics Anonymous [AA], NA), as an adjunct to treatment, seems to predict less cocaine use.[3,15] A newer voucher-based therapy has also been found to be effective in promoting abstinence.[70]

Amphetamines

Central nervous system stimulants have been used both with and without social acceptance for thousands of years. The Chinese prepared ephedrine-containing products from a plant called Ma-Huang (*Ephedra vulgaris*).[7] People in East Africa and the Arabian Peninsula chew the leaves of the khat bush (*Catha edulis*) for the stimulating effects of the alkaloid cathinone.[62] Caffeine is consumed worldwide in a usually socially acceptable manner in the form of

coffee and energy drinks. Amphetamine was synthesized in 1887, and methamphetamine in 1919. The legal sanctions against widespread prescribing of amphetamines in the 1970s restricted their supply and fostered a black market thriving on the illicit production of methamphetamine powder ("speed," "meth," "crank," and "crystal meth"). During the 1990s, California and the West Coast experienced a dramatic resurgence of methamphetamine-related hospital admissions, poison center calls, and law enforcement actions. Methamphetamine misuse has since become a nationwide problem, prompting government restrictions on retail sales of ephedrine and pseudoephedrine (precursor chemicals used in the manufacture of methamphetamine). A new marketing tool developed by savvy drug dealers aimed at younger, new users involves bright coloring and flavoring (strawberry, cola, cherry, and orange) added to crystal methamphetamine to help mask the bitter taste. According to the National Survey on Drug Use and Health for 2018, there were ~1.9 million people older than age 12 years who used methamphetamine in the previous year in America.[4]

PHYSICAL AND PSYCHOLOGICAL EFFECTS

CASE 90-7

Question 1: D.C., a college student, used amphetamine this past weekend when partying with his friends. He has a midterm examination in 2 days and is too tired to study, so one of his friends suggests snorting some more amphetamine and then hitting the books. D.C. finds amphetamine very much to his liking and begins to use it daily. He goes many days at a time without sleeping or showering and starts losing weight because he seldom has an appetite. He believes his friends are working with the DEA and tapping his phone.

Are these symptoms of a stimulant use disorder?

Methamphetamine produces CNS stimulation by enhancing the effects of norepinephrine, serotonin, and DA. This is accomplished by both blocking the reuptake and stimulating the release of these

neurotransmitters. These effects are greater for DA and norepinephrine than for serotonin.[50]

The powerful stimulating effects of amphetamine and methamphetamine have made their use popular among a wide variety of groups, including students, athletes, the military, dieters, and long-distance truck drivers. Initially, the user may experience alertness, euphoria, increased energy, the illusion of increased productivity, sociability, and decreased appetite. Continuous dosing, however, produces stereotypical grooming and other repetitive motions. Physiologic effects include bruxism, tremor, muscle twitching, mydriasis, hypertension, diaphoresis, elevated body temperature, nausea, dry mouth, weight loss, and malnutrition. Continued use for several days decreases productivity and is associated with disordered thoughts, paranoia, and psychosis. Tolerance develops very rapidly after continued use.[62]

Illicit methamphetamine is commonly insufflated or injected and, less commonly, taken orally. In a pattern similar to that seen with smoking cocaine, users freebase methamphetamine and smoke it. Heating the crystals and smoking the vapor of “crystal meth,” as with crack, is a common route of administration; however, snorting and IV administration are also used. Absorption is rapid after smoking, and the effects can last as long as 24 hours. Methamphetamine-induced psychosis may occur more frequently with smoking.

D.C. will probably be able to stay awake to study if he uses more methamphetamine; however, if he is up for too many days without sleep, his performance in the examination will suffer.

ADVERSE EFFECTS AND TOXICITIES

D.C. is exhibiting classic signs of chronic methamphetamine abuse, which will likely progress if he continues using it. A “speed freak” or “tweaker” (chronic methamphetamine user) is generally regarded even by other drug users as mentally unstable, aggressive, and emotionally labile, with unpredictable periods of violent, even homicidal, behavior. Chronic users characteristically develop complex paranoid delusional systems with hallucinations during

extended periods of intoxication that may involve several sleepless days and nights of continuous methamphetamine administration. This “speed psychosis” may include tactile hallucinations, such as formication (the sensation of something crawling under the skin). The initial treatment approach for stimulant-induced adverse psychological effects is nonpharmacologic. The distressed patient may be calmed by reducing environmental stimuli and using the “ART” approach developed by the Haight-Ashbury Free Clinic in San Francisco: *A*cceptance of the patient’s immediate needs; calm *R*eassurance that the condition is caused by the drug and will resolve eventually; and *T*alk down, which involves reassuring, reality-oriented communication.[64] An extremely agitated, anxious, psychotic user, however, will often require administration of a benzodiazepine, such as diazepam (10–30 mg orally or 2–10 mg via IM or IV administration) or lorazepam (2–4 mg orally or via the IM or IV route). Hypotension and respiratory depression are adverse effects associated with benzodiazepines, so concurrent use of alcohol or opioids may have synergistic effects. If psychosis persists, a high-potency neuroleptic, such as haloperidol (5–10 mg orally or via IM or IV administration) or risperidone (2–4 mg orally), is preferred owing to its minimal anticholinergic activity. Low-potency neuroleptics with higher anticholinergic activity such as chlorpromazine may worsen symptoms of delirium and hyperthermia.[64]

The physiologic toxicity of stimulant drugs includes hypertension, stroke, seizures, hyperthermia, sexual dysfunction, dental caries, rhabdomyolysis, renal failure, cardiac arrhythmias and cardiomyopathies, MI, and malnutrition.

The development of neurotoxicities involving dopaminergic and serotonergic neurons (possibly through interference with neurotransmitter biosynthesis, monoamine transport, increased production of reactive oxygen species, and apoptosis) has been demonstrated in animals. It also appears to cause permanent neuronal toxicity with prolonged use.[74,75]

WITHDRAWAL AND TREATMENT

CASE 90-7, QUESTION 2: D.C. is arrested for assault after a bar fight. He is held in the county jail and is unable to post bail. What withdrawal symptoms might he experience during incarceration?

D.C. will probably suffer intense cravings for methamphetamine and initial agitation, followed by fatigue and hypersomnolence. A withdrawal state after acute cessation of chronic stimulant use is generally the same as that previously described for cocaine. As with cocaine, the crash is notable for marked fatigue, depression, and anhedonia. Most symptoms are mild and will resolve within 1 to 2 weeks, although anhedonia and depression may persist.

Clinical studies investigating treatments for methamphetamine dependence are similar to that for cocaine treatments. Currently, no pharmacologic treatments have proved effective for methamphetamine dependence. The most effective treatment so far appears to be psychosocial therapies, such as CBT and contingency management.[64]

DISSOCIATIVE DRUGS: PHENCYCLIDINE, KETAMINE, AND DEXTROMETHORPHAN

Phencyclidine (phenylcyclohexylpiperidine [PCP]) and ketamine are arylcycloalkylamine, dissociative, anesthetic agents. PCP at one time was marketed as an IV anesthetic agent under the trade name Sernyl.[76] Subsequent reports of postanesthetic dysphoric reactions caused the drug to be withdrawn in 1965. It was reintroduced in 1967 as Sernylan and marketed as a veterinary anesthetic until 1978, when the manufacture and sale of the drug became illegal. Ketamine is currently used clinically as an anesthetic in both animals and humans. There is some data supporting its use in treatment refractory depression, but the common side effect of dissociation has

confounded the blinding of studies and is a significant side effect. More research is necessary, but it is possible that it could be used for very short-term treatment during the efficacy lag of established antidepressants.[77] Ketamine is shorter acting and somewhat less potent than is PCP.

Abuse of arylcycloalkylamines occurs primarily in large metropolitan areas. PCP is relatively easy to synthesize and is inexpensive; therefore, it is often misrepresented as other street drugs, such as lysergic acid diethylamide (LSD), amphetamine, mescaline, or Δ-9-tetrahydrocannabinol (THC). Ketamine ("K," "Special K," "Super K," or "cat valium") is commonly used as a "club drug," and is sometimes misrepresented as 3,4-methylenedioxymethamphetamine (MDMA; ecstasy). Ketamine is often diverted from veterinarian supplies. PCP ("angel dust" or "dust") in powdered form is often applied to parsley, marijuana ("dusted joint," "superweed"), or tobacco cigarettes and smoked. Oral, intranasal, and parenteral routes of administration are used by some. The combination of cocaine and PCP in a freebase smoking mixture is called "SpaceBase." Although ketamine is manufactured as an injectable liquid, it is frequently evaporated to a powder. The powder can be snorted or compressed into tablets.

Dextromethorphan is an antitussive agent found in some over-the-counter cough remedies. Its appeal as a drug of abuse may be because it is inexpensive, licit, lacks social disapproval associated with other drugs, and available over the counter, and abusers believe it to be safe because it is produced by a pharmaceutical company. Street names include "Skittles," "DXM," "Dex," "Robo," "C-C-C," and "Red Devils." Use is referred to as *dexing*, *robotripping*, and *robodosing*. Dextromethorphan is the D-isomer of the codeine analog of levorphanol. The metabolic byproduct of dextromethorphan, dextrorphan, has weak *N*-methyl-D-aspartate (NMDA) antagonist properties.[76] When dextromethorphan is ingested in large doses, it produces effects similar to that of PCP or ketamine. When abused, doses range from 300 to 1800 mg. The most commonly abused form is Coricidin® HBP Cough and Cold (called "C-C-C" on the street)

because it contains the highest concentration of dextromethorphan per dosage unit on the market (30 mg). Dextromethorphan is also available for sale on the Internet in powdered form, which can be ingested orally or snorted. The dextromethorphan "high" can last 3 to 6 hours, and can consist of euphoria, dissociation, hallucinosis, increased perceptual awareness, altered time perception, hyperexcitability, pressure of thought, and disorientation; increased blood pressure, heart rate, and body temperature; and blurry vision.[76] Other ingredients found in the over-the-counter preparations, such as acetaminophen, chlorpheniramine, guaifenesin, and alcohol, may be problematic when ingested in large doses. PCP is considered the typical dissociative drug, and review of its effects largely applies to ketamine and dextromethorphan as well.

Phencyclidine

PHENCYCLIDINE INTOXICATION

Persons who use PCP at a dose of ≥0.05 mg/kg may appear agitated, diaphoretic, and disoriented. There is an increase in blood pressure, pulse, and temperature, and the person may experience vertical and horizontal nystagmus. These symptoms can last for up to 2 days, even though the half-life of this drug is ~21 hours.[78] PCP and ketamine are noncompetitive antagonists of the NMDA receptor subtype of the major excitatory neurotransmitter, glutamate. Based on this pharmacologic mechanism, PCP is also used as an animal model of schizophrenia.[79] The dose, route of administration, and serum concentration of PCP all influence the pharmacologic effects of this drug and, thus, the symptoms of intoxication.[76] PCP in low doses causes inebriation, ataxia, changes in body image, numbness, and a mind–body dissociative feeling. Horizontal or vertical nystagmus or both are often present, and the anesthetic effect of the drug raises the pain threshold. Amnesia can occur after intoxication.

As the dose of PCP increases, the patient may manifest agitation, combativeness, catatonia (ketamine users refer to this as a "k-hole"), and psychosis. The action of PCP on the autonomic nervous system

becomes more prominent and is characterized by a confusing combination of adrenergic, cholinergic, and dopaminergic effects. A hypertensive response is typically encountered. Tachycardia, tachypnea, and hyperthermia may also be noted in the moderately intoxicated patient. The agitated, combative patient often has feelings of great strength. This, combined with the anesthetic effect of PCP, can result in serious injury because there is no pain sensation to stop the physical activity.

With large doses of PCP, marked CNS depression occurs, and nystagmus may no longer be present. In addition to the physiologic effects noted earlier, respiratory depression, seizures, acidosis, and rhabdomyolysis may further compromise the patient's condition. Rhabdomyolysis, particularly in the presence of acidemia, can result in acute renal failure.[64] Opisthotonic posturing and muscular rigidity occur frequently in the severely intoxicated patient.

MEDICAL MANAGEMENT OF INTOXICATION

Diagnosis of PCP intoxication should be confirmed through a blood or urine specimen. Currently, no clinically useful antidote to PCP exists, and treatment should be supportive. Environmental stimuli should be minimized, and airway support should be maintained. Even attempts to talk down the patient may trigger a combative response, and chemical restraints may be indicated. Physical restraints may increase the risk of rhabdomyolysis and should be reserved for patients who pose a threat of great danger to themselves or others. Benzodiazepines are useful in the management of the anxious, agitated patient with mild-to-moderate PCP intoxication. If benzodiazepines are insufficient, haloperidol (5 mg IM) is effective.[64] Low-potency neuroleptics should be avoided because a greater possibility of precipitating a hypotensive response or a seizure exists.

Hypertension may be managed with β-blockers or calcium channel blockers. Diazepam (5–10 mg IV to 30 mg total) is a useful anticonvulsant for the management of PCP-induced seizures.[64] Because extreme agitation, seizures, and hyperthermia can initiate

rhabdomyolysis and secondarily cause myocardial, renal, or hepatic dysfunction, use of anxiolytics, neuroleptics, anticonvulsants, and cooling measures should be as needed.

The urinary excretion of PCP (a basic compound) is enhanced when the urine is acidic; however, this approach is not recommended because it may exacerbate myoglobinuric renal failure.[54] Activated charcoal in a dose of 50 to 150 g initially, then 30 to 40 g every 6 to 8 hours, can prevent the intestinal reabsorption of this drug and promote its elimination.[64]

PSYCHOLOGICAL AND PROLONGED EFFECTS

Chronic PCP use can result in prolonged residual psychological symptoms, including anxiety, depression, and psychosis.[64] Pharmacotherapy for these symptoms may be necessary. Prolonged psychiatric sequelae are almost always associated with premorbid psychopathology. Perceptual disorders, including auditory and visual hallucinations, such as after images seen following moving objects ("trails"), may also occur. Flashbacks (discussed in detail in the subsequent section on Lysergic Acid Diethylamide) have been reported after PCP use.

The *DSM-5* does not recognize PCP withdrawal; however, about one-fourth of heavy PCP users report symptoms after discontinuation of use.[64] These symptoms include depression, anxiety, irritability, hypersomnolence, diaphoresis, and tremor. Animal studies have described a withdrawal syndrome, but it is unclear whether a true withdrawal syndrome occurs in humans.[64] Currently, no pharmacologic treatments for PCP use disorder exist. Some animal data indicate neurotoxicity; however, the long-term consequences and significance for humans are unknown, and require further study. Irritability and a feeling of isolation are common, and memory lapses, speech and visual disturbances, and confusion have been reported in long-term users as well. Memory lapses, speech and visual disturbances, and confusion have been described in long-term users as well.

HALLUCINOGENS

Hallucinogens can be categorized as indole alkylamines (eg, LSD, psilocybin, and dimethyltryptamine) or phenethylamines (eg, mescaline and MDMA). LSD is considered the prototype hallucinogen. Although MDMA is classified as a phenethylamine, it has structural similarities to amphetamine and mescaline. It has been labeled an entactogen or empathogen because of its strong empathy-producing effects and mild hallucinogenic effects. The term *entactogen* can be translated as "a touching within." Hallucinogens are commonly referred to as *psychedelics*.

In 2018, 5.6 million Americans older than age 12 years were reported to be hallucinogen users.[4] The popularity of MDMA (ecstasy, X) has risen dramatically in recent years, partly because of its use as a "club drug." The usual pattern of use for hallucinogens is occasional self-administration for enhancement of recreational activities, such as dancing, or for "mind expansion." Certain individuals may develop psychological dependence and use hallucinogens in a more chronic and compulsive manner.

Lysergic Acid Diethylamide

EFFECTS

Perhaps the most famous of all hallucinogens, LSD-25 was first synthesized by Albert Hofmann of Sandoz Laboratories in 1938. It was developed as an analeptic agent, but produced significant uterine stimulation and caused experimental animals to become excited or cataleptic. Five years later, while resynthesizing LSD-25 for further pharmacologic testing, Dr. Hofmann experienced a restlessness that forced him to go home. This was followed by 2 hours of intense visual hallucinations of kaleidoscopic images and colors. Later, he identified LSD-25 as a potent hallucinogen. Clinical experimentation produced hundreds of papers describing LSD as a drug that could facilitate psychotherapy, particularly in the

management of addictive behavior. Widespread public self-experimentation with LSD for recreation and self-exploration, coupled with growing attention to adverse psychological consequences, led Sandoz to discontinue production of LSD-25 (as well as psilocybin, psilocin, and related congeners) in August 1965. The United States made LSD a Schedule I controlled substance in 1970 after the proliferation of illicit suppliers to meet the huge public demand for this drug.

Although the mechanism of action of classic hallucinogens is not fully understood, they appear to predominately act as agonists or partial agonists at serotonin (5-hydroxytryptamine [5-HT]) receptors, specifically the 5-HT_2 receptor.[80] LSD, one of the most potent hallucinogens known, is active at doses of 25 to 250 µg. Most users take about 100 to 150 µg of LSD for a significant effect. This dose produces mild-to-moderate sympathomimetic effects, profound visual hallucinosis, and the sensation of disordered integration of sensory input. For example, sounds and music are perceived as visual imagery, odors are felt, and inanimate objects assume lifelike qualities. In addition to these sensory–perceptual effects, psychic effects occur, such as depersonalization, dreamlike feelings, and rapid alterations of affect. These are accompanied by somatic effects, including dizziness, nausea, weakness, tremor, and tingling skin.[80] These combined effects begin within an hour of ingestion of LSD, and usually peak in intensity during the first 2 to 4 hours. After taking LSD, most people feel they have returned to a normal psychological state by 10 to 12 hours.[81] Within an hour of ingestion, a person will begin to experience altered sensations of his/her surroundings, in addition to some psychic and somatic effects.

ADVERSE EFFECTS

The most frequently encountered adverse reaction associated with the hallucinogenic drugs is a mental state of acute anxiety and fear, typically referred to as a “bad trip.” The hallucinogen experience is influenced by set (the user’s mental state and expectations of drug effects) and setting (the environment in which drug use takes place,

including the social conditions). Users may be able to calm themselves without outside intervention. The initial therapy for people undergoing a bad trip is frequently called “reality therapy” and consists of talking down the fear and panic. This consists of getting the person to a quiet, relaxed setting and helping him or her focus on explanations for the uncertainties that are causing the panic. This process also tends to reassure the person that he or she is in a safe physical environment and that the drug effects will diminish in a few hours. Most of these bad trips are resolved during the state of intoxication (generally, 6–12 hours), but some last as long as 24 to 48 hours.[64]

If the talk-down approach is not successful in resolving the panic, drug therapy can be considered. Sedation with an oral benzodiazepine (ie, diazepam 10–30 mg) or a parenteral benzodiazepine (ie, lorazepam 2 mg IM) will frequently alleviate the panic.[64] Supportive talking down should be continued because the benzodiazepine will not stop the trip; it will simply sedate the patient. Haloperidol 2 mg IM may also be used if benzodiazepines are insufficient. Phenothiazines should not be used for initial management of bad trips because they have been associated with poor outcomes.[64]

Regarding adverse physical effects, classic hallucinogens have a high margin of safety, although patients should be monitored for seizures or elevations in body temperature, which may indicate a potential hyperthermic crisis. Anticonvulsant therapy may not be effective until body temperature has been lowered.[64] Conditions such as pregnancy and epilepsy serve as absolute contraindications for LSD use.

FLASHBACKS AND LONG-TERM EFFECTS

Use of hallucinogens can trigger a transient psychosis or unmask an underlying psychiatric disorder; however, a true psychotic episode is rare. Psychiatric conditions that persist more than a month after hallucinogen use are likely caused by preexisting psychopathology.[64]

Hallucinogen use does not seem to be associated with any cognitive impairment.[81]

Hallucinogen persisting perceptual disorder (HPPD), commonly referred to as *flashbacks,* is characterized by recurrences of part or all of the hallucinogenic drug experiences after a period of normal consciousness in a person who used the drug previously. The flashbacks may last from minutes to days or months (usually a few hours). The estimated prevalence of flashbacks varies widely in studies, and the etiology is still unclear.[82] Flashbacks can occur spontaneously or be triggered by exercise, stress, or another drug (eg, marijuana).[81] Treatment remains anecdotal; no randomized, controlled trials have evaluated the efficacy of pharmacotherapy for HPPD.[83]

LSD and other classic hallucinogens have low potential for chronic use disorder. There does not appear to be a clinically important withdrawal syndrome associated with their use. The rapid development of tolerance that occurs with these drugs may explain the intermittent use patterns commonly seen.

3,4-Methylenedioxymethamphetamine

CASE 90-8

Question 1: R.X. and her friend P.B. go to "raves" (all-night dance parties) every weekend and usually take ecstasy (MDMA). R.X. says it makes her feel like "I love everyone around me," and P.B. likes to be able to "dance all night without getting tired."

Are these effects common with MDMA?

Merck Pharmaceuticals (Boston, MA) patented MDMA in 1914, but it was not until the 1950s that its use was examined in animal studies when the U.S. Army Intelligence investigated it as a "brainwashing" agent. By the late 1970s, a few therapists and psychiatrists began using the drug with reported success in patients with a wide range of conditions.[84] MDMA produces a very manageable and comfortable entactogenic effect, during which the person has a clear sensorium.

The experience can be recalled in detail, and the insights gained during the session can be incorporated into normal life. The public gave several names to this drug, such as ecstasy, XTC, Adam, and M&Ms. The media became aware of the anecdotal reports from both psychiatrists and people self-experimenting with MDMA. In 1985, the DEA made MDMA a Schedule I drug. Subsequently, supplies of the drug proliferated in the public illicit marketplace, and its popularity soared. In 2001, after successful lobbying by researchers interested in reinstituting MDMA in clinical practice, the FDA granted approval for a pilot study investigating the therapeutic use of MDMA in the treatment of post-traumatic stress disorder (PTSD). Results of this placebo-controlled study indicate that MDMA is very effective (83% vs 25%) in treating PTSD.[85] The effects of MDMA are mainly exerted by three neurochemical mechanisms: blockade of serotonin reuptake, stimulation of serotonin release, and stimulation of DA release.[86] The common psychological effects of MDMA intoxication include an overall heightened sense of empathy, interpersonal closeness, increased acceptance of others, and a powerful sense of well-being.[87] The experience is influenced by set and setting. The amphetamine-like side effects include mydriasis, tachycardia, sweating, increased energy and alertness, bruxism, nausea, and anorexia.[88,89] Users generally ingest MDMA in tablet form, and the onset of action is usually after 30 to 60 minutes. Some users take a "booster" dose after 2 hours. The usual duration of action of MDMA is 4 to 6 hours, and the half-life is ~8 hours. MDMA users in the rave scene often "stack" multiple doses, and polydrug use is common. The combined use of ecstasy and LSD is referred to as *candy flipping*.[86]

R.X.'s feelings of love for everyone are consistent with the empathogenic effects of MDMA, whereas P.B. is enjoying the amphetamine-like effects of increased energy to dance all night.

ADVERSE EFFECTS

Case 90-8, Question 2: Several hours after taking MDMA, P.B. is still dancing. She begins to feel hot and realizes she is profusely sweating. On her way to the bar for a drink, she begins to feel confused and collapses to the floor. Her friends witness her having a seizure and call 9-1-1. What is happening to P.B.?

The rave scene, with its crowded conditions and often-high ambient temperatures, has contributed to many adverse effects associated with MDMA ingestion. Because of their increased physical activity, the ravers may become dehydrated. In addition, supplies of MDMA have been notoriously unreliable. Many other drugs have been misrepresented as MDMA, including other phenethylamines such as 3,4-methylenedioxyamphetamine (MDA) and paramethoxyamphetamine (PMA); amphetamine; cocaine; opiates; ketamine; and dextromethorphan. The common polydrug use practiced at raves compounds the problem. Dextromethorphan taken at high doses for its dissociative properties competes with MDMA for hepatic metabolism, and its anticholinergic effects block perspiration, potentially leading to overheating.[84]

The most dangerous adverse physical effect of MDMA is hyperthermia. MDMA has a slight affinity for the 5-HT_2 receptor, and the increased body temperature may be the result of this activation.[86] The hyperthermia has led to rhabdomyolysis, acute renal and hepatic failure, disseminated intravascular coagulation (DIC), and death.[90] DIC has been the most common cause of death. Treatment of hyperthermia involves cooling measures and IV fluids. Benzodiazepines (eg, lorazepam 2 mg IM or IV) and dantrolene (1 mg/kg IV) may be helpful. Other adverse physical effects can include hypertension, cardiac arrhythmias, convulsions, cerebrovascular accident, hepatitis, and hyponatremia (from overingestion of water as a harm reduction measure to avoid hyperthermia).[89,90] In 2011, there were 22,498 ED visits associated with MDMA use.[91] Adverse psychological effects are also possible, including anxiety, depression, panic attacks, agitation, paranoia, and, rarely, psychosis. The treatment of these psychological adverse effects is the same as that for those associated with the classic hallucinogens, including

talk-down therapy and benzodiazepine administration. Water restriction and administration of hypertonic saline are indicated in seizures resulting from hyponatremia.[88] P.B. may be suffering from MDMA-induced hyperthermia and needs urgent medical evaluation.

LONG-TERM EFFECTS

Case 90-8, Question 3: R.X. has read in the newspaper that MDMA is associated with "brain damage" and is worried that she has caused permanent damage to her brain. What are the long-term effects of MDMA?

Animal studies have consistently demonstrated long-term MDMA-induced serotonin depletion. This has been evidenced by lower levels of serotonin, decreased metabolite levels, lowered levels of tryptophan hydroxylase, and loss of serotonin reuptake transporters.[84] This may explain the induction of panic attacks for chronic users. MDMA damages serotonin axonal projections; axonal resprouting and regeneration do occur, but it is unclear whether these new projections are damaged.[84,92] Both hepatotoxicity and neuronal toxicity occur with MDMA use, and is suspected to be due to oxidative stress, mitochondrial dysfunction, and excitotoxicity.[74]

Several retrospective studies in humans have claimed lowered cognitive performance in MDMA users compared with nonusers. These studies have confounding variables, such as other drug use and adulterant exposure and lifestyle factors.[84,92]

Use of MDMA does not appear to produce physical dependence, but some users may become psychologically dependent. Tolerance to the empathogenic effects develops rapidly and may last 24 to 36 hours. This may explain, in part, the more common practice of sporadic dosing of the drug.[64,87] No distinctive withdrawal syndrome that would require pharmacologic treatment has been described.

CANNABINOIDS

Marijuana is the most widely used illicit substance in the United States. In 2018, 43.5 million Americans ages 12 years or older reported using marijuana in the past year.[4] The main psychoactive ingredient in the *Cannabis sativa* plant is THC, although the plant is known to contain >70 cannabinoids.[93] The other main constituent is cannabidiol (CBD).

Researchers in cannabinoid neurobiology have discovered two cannabinoid receptors in the CNS: CB_1 and CB_2; however, additional receptors have been proposed. Research has demonstrated that the main psychoactive and addictive effects are almost completely mediated by the CB_1 receptor.[94] In addition, five endogenous cannabinoids (endocannabinoids) that act at the cannabinoid receptors have been discovered.[95] The best known are arachidonic acid ethanolamide (anandamide) and 2-arachidonoylglycerol (2-AG).[95] Considerable evidence exists supporting the role of THC–opioid interactions with enhanced antinociception. Cannabinoids have been shown to release endogenous opioids, and cannabinoid receptors colocalize with substance P (the neurotransmitter responsible for transmitting pain information) receptors in the striatum. CBD is primarily active at CB_2 receptors. It is also active at both serotonin and glycine receptors, making them more sensitive to the neurotransmitters. It has been shown to not have psychoactive effects and can block this effect derived from THC.[96,97]

A synthetic THC, dronabinol, and an analog of THC, nabilone, are available if clinicians want to prescribe this chemical. CBD is available by prescription under the brand name Epidiolex® and is FDA approved for Lennox–Gastaut and Dravet syndromes. It is available if the clinician desires to use this molecule in the patient for off-label purposes. Availability of prescription versions of these molecules eliminates the need for clinicians to recommend “medical marijuana” because it avoids the risks associated with dispensary marijuana such as adulteration, dose inconsistency, and unwanted effects.

Effects

CASE 90-9

QUESTION 1: P.H. is a 16-year-old male who is offered a marijuana cigarette (joint) by one of his friends. He smokes it and begins to feel light-headed and euphoric. He begins laughing at everything around him. Thirty minutes later, he and his friend become very hungry ("the munchies") and eat several candy bars.

Which of P.H.'s symptoms are consistent with marijuana use?

THC rapidly distributes into fat deposits and has an elimination half-life of 1.3 days in infrequent users and up to 13 days in frequent users.[98] Time to maximum (T_{max}) concentration via inhalation is rapid, occurring from 3 to 10 minutes, whereas the oral ingestion will take up to 2 hours.[98] Anecdotal comments from users are that the inhalation method has the advantage of more accurate dose administration because of its rapid effects. The oral version's delay in T_{max} can result in patients ingesting more than they wanted because of the inability to assess the "high" in a timely manner. The pharmacologic effects sought by most users of cannabis products are sedation, mental relaxation, euphoria, and mild hallucinogenic effects, and these effects depend on set and setting. Other common effects that are usually perceived as pleasurable include silliness, subjective slowing of time, gregariousness, hunger, and mild perceptual changes of all the senses that engender an absorbing fascination with music, eating, and other sensual and sensory activities. The state of mind generated is referred to as *stoned*, *high*, *loaded*, *wasted*, and many other colloquial terms. Smoking marijuana typically causes numbness and tingling of the extremities, light-headedness, loss of concentration, and a floating sensation in the first 3 or 4 minutes. Some of these effects are probably caused by the hyperventilation associated with deep inhalation of the smoke (referred to as a *hit* or *toke*) and breath-holding to allow maximal absorption from the lungs. During the first 10 to 30 minutes, the user may experience tachycardia (possibly palpitations), mild diaphoresis,

conjunctival injection ("red eye"), drying of the mouth, weakness, postural hypotension, periods of tremulousness, incoordination, and ataxia along with euphoria and the mental effects described earlier. There is a positive correlation of an increased risk of MI, likely due to hypotension and tachycardia.[99]

These effects usually resolve by 1 to 3 hours and are followed by a 30- to 60-minute period of sleepiness before complete clearing and return to normal consciousness. Oral ingestion of cannabis products may delay the onset of effects by 45 to 60 minutes and prolong the duration.[94] P.H. is experiencing euphoria, giddiness, and increased appetite, consistent with marijuana intoxication.

Adverse Effects

Case 90-9, Question 2: P.H. smokes more marijuana with his friend. He liked it so much the first time that he decides to take several "hits" this time. He begins to think his friend is laughing at him, and notices his heart is beating rapidly. He starts to panic. Is P.H.'s reaction caused by the marijuana?

Consistent with its widespread use, marijuana was the second most frequently mentioned illicit substance in ED episodes in the United States in 2011. A total of 455,668 marijuana-related ED visits were reported in 2011.[65] These visits include marijuana in combination with other drugs. As the percentage of THC in marijuana has increased, so have the ED visits. The majority of ED visits are from unexpected reactions, such as anxiety, paranoia, and panic attacks. Despite these numbers, there are no documented cases of fatality in humans from marijuana OD, and adverse effects tend to be self-limiting, and often do not require medical treatment.

A syndrome consisting of anxiety, paranoia, depersonalization, disorientation, and confusion that can lead to panic states and incapacitating fear is perhaps the most frequently reported adverse effect of marijuana. Comforting reassurance (talk down) and reducing stressful stimuli can alleviate this condition. The dysphoria and anxiety usually resolve in a few hours or less with such an

approach. More severe incidents that evolve into panic reactions not resolved by sympathetic counseling may be relieved with oral benzodiazepine therapy in a dose equivalent to 5 to 10 mg of diazepam.[64] These adverse psychological reactions to cannabis products commonly occur with inexperienced users, high doses, concomitant use of other psychoactive drugs, and overtly stressful situations. Severe reactions requiring pharmacologic therapy are rare. A review of the literature found that cannabis use increases the risk of developing psychotic disorders. This is more severe among vulnerable or predisposed individuals and negatively affects the course of preexisting chronic psychosis.[100]

Other adverse effects can include slowed psychomotor responses and short-term memory loss. Slowed psychomotor responses have been shown in certain groups of acutely intoxicated subjects and chronic users. There has been a steep increase in automobile accidents among marijuana users. A reduction in reaction time, attention, and other executive functions necessary for driving are all impaired, and this may last for days.[101] Short-term memory loss is a frequently documented acute, reversible effect of marijuana intoxication as well.

The paranoid ideation and panic reaction of P.H. could certainly be caused by a high THC dose and his inexperience with marijuana.

Cannabis withdrawal will occur in persons who have been using the substance nearly daily over at least a few months, and these symptoms will occur in up to 87% of users.[64,94,102] The symptoms will typically occur about a week after cessation and consist of (a) irritability, anger or aggression; (b) nervousness or anxiety; (c) sleep difficulties; (d) decreased appetite or weight loss; (e) restlessness; (f) depressed mood; and (g) physical symptoms such as abdominal pain, shakiness, sweating, fever, chills, or headache.[1] Treatment is not generally necessary, but dronabinol has shown benefit in reducing the distress.[103]

Long-Term Effects

Case 90-9, Question 3: P.H. continues to smoke marijuana daily. What are possible long-term effects of marijuana use?

Chronic use of cannabis has been shown to produce an "amotivational syndrome" characterized by apathy, lack of long-term goal achievement, inability to manage stress, and generalized laziness.[94,104,105] Cognitive impairment can occur from chronic marijuana use, including executive functioning, cognitive processing speeds, and short-term memory loss that is not reversible.[106] Adolescents are at risk for a reduction in intelligence quotient (IQ) related to marijuana use that does not reverse even after 1 year of abstinence.[102] The impairment is more pronounced the longer the drug is used.[85] Other concurrent drug use may also contribute to cognitive impairment associated with marijuana use. As noted earlier, there is a dose-dependent risk of chronic use resulting in an increased risk of developing a psychotic illness later in life.[100,107] Adolescents using THC weekly showed an increase in paranoia by 133% and hallucinations by 92% over non–THC-using adolescents.[108] Those older than age 18 showed a 380% increase of developing a psychotic disorder if using marijuana daily.[109] This increased to nearly 500% as the potency of THC increased.[109]

Chronic users will have worse periodontal health.[106] The pulmonary complications of chronic heavy marijuana use are potentially significant. Chronic cough, sputum, wheezing, bronchitis, and cellular changes typical of chronic tobacco smokers are reported in chronic cannabis smokers.[94,110] THC has been shown to be a potent bronchodilator. Both oral and smoked THCs were shown to produce significant bronchodilation when given to healthy subjects. The bronchodilatory response in asthmatics given THC has been shown to be less vigorous.[111] Tolerance to these effects can develop after some weeks, and chronic marijuana smoking results in increased airway resistance and decreased pulmonary function.[94] Many of the same carcinogens in nicotine cigarettes are also found in marijuana smoke, and risk of some cancers is increased compared to nonusers.[94,105] *Aspergillus*-contaminated marijuana has

been reported to cause pulmonary fungal infections in immunocompromised patients, who may be using the drug for its medicinal value.[112]

Tolerance to the psychoactive effects of marijuana does develop. Chronic users may not experience the full range of effects as do new users unless they abstain for several days or weeks to regain initial sensitivity to the cannabis, and chronic users can tolerate large doses that generally are toxic to novices. Tolerance develops rapidly to both physiologic and psychological effects of cannabis. Dependence characterized by a physical withdrawal syndrome occurs after chronic high-dose use of cannabis. Dysphoria and malaise similar to that experienced with influenza can also occur. The cumulative dose of cannabis and duration of use necessary to produce dependence is unknown. The withdrawal syndrome is generally mild and self-limiting, and pharmacologic treatments usually are not required.

Marijuana has been labeled as a "gateway drug," meaning that it will lead to the use of "harder" drugs, such as cocaine or heroin. Marijuana is the most widely used illicit drug, but use of drugs such as alcohol and tobacco often predates marijuana use. No studies have conclusively demonstrated a causal link between marijuana use and subsequent other drug use.[94]

There are clear acute and chronic risks associated with marijuana use that is primarily related to THC content and ingestion via inhalation. Dronabinol, nabilone, and CBD have FDA indications, and can be prescribed by a clinician if this is the desired pharmacology, yet marijuana has none. Despite this, many patients claim a "medical" benefit from this plant. Pharmacists are uniquely positioned to help patients understand the definitive risks from marijuana use and provide alternatives to their conditions that have FDA approvals.

INHALANTS

The introduction of anesthetics (nitrous oxide, chloroform, and ether) to medicine in the early 1800s also promoted the widespread and popular recreational use of these inhalants for mind-altering recreational purposes. Today, abused inhalants include a wide variety of chemicals that are found readily in homes or workplaces, or purchased at retail establishments. Inhalants are commonly subdivided into three main categories: the volatile solvents (mostly hydrocarbons); volatile nitrites (amyl, butyl, isobutyl, and cyclohexyl); and nitrous oxide (laughing gas). The fumes or vapors of these liquids, or paste, in the case of glue, are directly inhaled out of their containers (“sniffing”); poured onto a rag that is held to the nose (“huffing”); poured into a plastic bag (“bagging”); or merely cupped in the hands and inhaled. Aerosols and gaseous substances such as nitrous oxide are also used to inflate a balloon and then inhaled out of the balloon by the user. These products can also be ingested orally or sprayed directly into the mouth. Volatile solvents include gasoline, toluene, kerosene, alcohols, airplane glue, lacquer thinner, acetone (nail polish remover), benzene (nail polish remover, model cement), naphtha (lighter fluid), plastic cement, liquid paper (ie, White Out, [Emraw, New York City, NY] usually containing 1,1,1-trichloroethane, also trichloroethylene, and perchloroethylene), and many others. The volatile nitrites, once widely available, are prohibited by the Consumer Product Safety Commission, but can still be found, sold in small bottles, labeled as “video head cleaner” or “room odorizer.” Amyl nitrite is used medically as a vasodilator for treatment of angina, and requires a prescription. The volatile nitrites are commonly referred to as *poppers*, because of the sound made when an ampule of amyl nitrite is broken open. The most commonly used inhalants are glue, shoe polish, toluene, and gasoline.[113] The use of multiple products is common. Silver and gold paints are popular because they contain more toluene than do paints of other colors.[114]

Inhalant use is most common among younger individuals (consistently highest annual prevalence among eighth graders), and tends to decline as youth grow older. The decline likely reflects that other drugs become available and are substituted. Abuse of

inhalants is believed to be popular among children and adolescents because of their low cost, easy availability, rapid onset, and low threat of legal intervention. In addition, they are easily concealed. The 2019 Monitoring the Future (MTF) study found that 9.5% of 8th, 6.8% of 10th, and 5.3% of 12th graders have abused inhalants.[115] These surveys, most of which are administered in schools, likely underestimate the true prevalence, as a small but high-risk group (incarcerated, homeless, and transient adolescents) are not included in the surveys.

Effects of Inhalants

Inhalant abuse includes a broad range of chemicals, and they likely have different pharmacologic effects. In fact, the mechanisms of action of the volatile inhalants are poorly understood. Nearly all have CNS depressant effects. Evidence from animal studies suggests that the effects and mechanism of action of volatile solvents are similar to those of alcohol and sedative-hypnotics.[116]

Gases and vapors are rapidly absorbed when inhaled, and, because of their high lipophilicity, tend to distribute preferentially to lipid-rich organs such as the brain and liver.[116] Expired air is the major route of elimination, and most are metabolized to some extent. Inhalation of these products produces a temporary stimulation and reduced inhibitions before the depressive CNS effects occur. Acute intoxication is associated with euphoria, giddiness, dizziness, slurred speech, unsteady gait, and drowsiness.[114] As the CNS becomes more deeply affected, illusions, hallucinations, and delusions develop. The user experiences a euphoric, dreamy high that culminates in a short period of sleep. The intoxicated state lasts a few minutes, but users may continue to inhale repeatedly for several hours. Nitrous oxide is an antagonist of the NMDA subtype of the glutamate receptor.[76] Its pharmacologic effects are poorly understood. It produces euphoria and symptoms of intoxication similar to those described for the volatile solvents.

The major effect of the volatile nitrites is the relaxation of all smooth muscles in the body, including the blood vessels. This usually allows a greater volume of blood to flow to the brain. The onset of effects takes 7 or 8 seconds, and the effects last about 30 seconds. A certain “rush” occurs, which may be followed by a severe headache, dizziness, and giddiness. The volatile nitrites are frequently used in the context of sexual activity, because of the effect of increased tumescence and relaxation of smooth muscle.[116]

Acute and Chronic Toxicities Associated With Inhalants

The wide variety of chemicals inhaled causes a tremendous range of toxicities. Toxicity depends on the chemical, and on the magnitude and duration of exposure. Complications can result from the effects of the solvents or other toxic ingredients, such as lead in gasoline. The lipophilicity of the volatiles enhances their toxicity. Injuries to the brain, liver, kidney, bone marrow, and, particularly, the lungs can occur, and they may result from the effect of heavy exposure or hypersensitivity. Inhalant abusers may develop irritation of the eyes, nose, and mouth, including rhinitis, conjunctivitis, and rash.[116] Methemoglobinemia has been associated with volatile nitrite use.

Deaths from inhalant use are well documented and may occur from OD or trauma (falls, drowning, and hanging). Death from OD is often caused by respiratory problems or suffocation after CNS depression.[116] Deaths caused by asphyxiation, convulsions, coma, and aspiration of gastric contents have occurred.[114] Acute cardiotoxicity resulting in cardiac arrest may cause sudden death. Referred to as *sudden sniffing death*, it is likely caused by sensitization of the myocardium to catecholamines, exacerbated by physical exercise, resulting in fatal ventricular arrhythmias.

Many of the inhalants produce neurotoxicity, which can range from mild impairment to severe dementia. Neurologic deficits include cognitive impairment, ataxia, optic neuropathy, deafness, and disorders of equilibrium. Loss of white matter, brain atrophy, and

damage to specific neural pathways can result from chronic exposure to some inhalants. Some damage to the nervous system and other organs may be at least partially reversible when inhalant use is discontinued.[114]

Inhalant Abuse and Dependence

Compulsive use has been documented with inhalants, although inhalant abuse and dependence is a neglected area of research. Animal studies have shown some of the abused inhalants to have reinforcing properties.[116,117] It is unclear whether a true withdrawal syndrome occurs with chronic use of inhalants. Inhalant use is typically episodic in nature, and thus users may not be exposed to levels with sufficient frequency necessary to develop physical dependence or tolerance.

ALCOHOL USE DISORDERS

Alcohol Content and Definitions

Beverages containing alcohol (ethanol) have a wide range of ethanol content. Alcoholic proof is a measure of how much ethanol is in an alcoholic beverage and is twice the percentage of alcohol by volume (ABV), the unit that is commonly used as percent (%). Therefore “80 proof” is 40% ABV, and pure alcohol (100%) is “200 proof.” One hundred percent ethanol does not stay 100% because it is hygroscopic and absorbs water from the atmosphere.

Legally, in the United States, beers containing up to 0.5% ABV can be called nonalcoholic. Light beers range from 2% to about 4% ABV; beers range from 4% to 6% ABV; ales, stouts, and specialty brews can be as high as 10% ABV. Wines are produced at about 14% to 16% (28–32 proof), because that is the point in the fermentation process at which the alcohol concentration denatures the yeast. Stronger liquors are distilled after fermentation is complete to

separate the alcoholic liquid from the remains of the source of sugar (eg, grain and fruit). Distilled liquor cannot be stronger than 95% (190 proof). A standard drink in the United States is considered to be 0.5 oz or contain 15 g (0.5 fL oz of absolute alcohol) of alcohol. This is equal to 12 oz (355 mL) of 5% beer, 5 oz (148 mL) of 12% wine, or 1.5 oz (44 mL) of 40% spirits.[118,119]

Epidemiology

Slightly more than half (51.1%) of Americans age 12 or older reported being current drinkers (at least one drink in the past 30 days) of alcohol in the 2018 National Survey on Drug Use and Health survey.[4] This translates to an estimated 139.8 million people, which is similar to the estimates from 2002 to 2017. In 2018, heavy drinking (five or more drinks on the same occasion on each of 5 or more days in the past 30 days) was reported to be 24.5% of the population age 12 or older, stable since 2015.[4]

Approximately 10% of Americans will be affected by alcohol use disorder (AUD) sometime during their lives.[120,121] Treatment of alcohol dependence consists mainly of psychological, social, and pharmacotherapy interventions aimed at reducing alcohol-related problems.[122,123] Treatment usually consists of two phases: detoxification and maintenance.

The rationale for pharmacotherapy is based on several considerations. Advances in neurobiology have identified neurotransmitter systems that initiate and sustain alcohol drinking; pharmacologic modification of these neurotransmitters or their receptors may alter dependence.[124] Promising genetic research confirms that alcoholics are a heterogeneous population and that several gene variations can predispose some to increased alcohol use, whereas other gene variations can confer protection.[124] Animal models have identified pharmacologic agents that reduce alcohol consumption in animals, suggesting that similar agents could reduce alcohol consumption in humans.

Risks and Benefits of Alcohol Consumption

The role of alcohol in the development of medical problems such as cardiovascular disease, hepatic cirrhosis, and fetal abnormalities is well documented. Alcohol use and abuse contribute to thousands of injuries, auto collisions, and violence.[125] Alcohol can dramatically affect worker productivity and absenteeism, family interactions, and school performance.[126] Some studies suggest, however, that individuals who abstain from using alcohol may also be at greater risk for a variety of conditions, particularly coronary heart disease (CHD), than do people who consume small-to-moderate amounts of alcohol.[127]

A number of studies have documented an association between moderate alcohol consumption and lower risk of CHD and MI.[128,129] Binge drinking after an MI, however, increases the risk of mortality.[130,131] U.S. guidelines define moderate drinking as one drink or less daily for females or people age 65 and older, and two drinks or less per day for males.[132] An association between moderate drinking and lower risk of CHD does not mean that alcohol is the cause of the lower risk. A review of population studies indicates that the higher mortality risk among abstainers may be attributable to socioeconomic and employment status, mental health, and overall health, rather than abstinence from alcohol use.[133] Benefits of moderate drinking on CHD mortality are offset at higher drinking levels by increased risk of death because of other types of heart disease, cancer, cirrhosis, and trauma. The risk of a disease outcome from low-to-moderate drinking is less than the risk from either no drinking at all or heavier drinking. This produces a U-shaped curve when examining the association of alcohol consumption with rates of deaths from all causes.[127]

The exact mechanism by which alcohol use may be protective against morbidity in those with CHD is not clear. Some evidence indicates that different types of alcoholic beverages, such as red wines, which are high in tannins, may lower blood lipids and fats by increasing antioxidants.[131] Specifically, the mechanisms by which alcohol may reduce the risk of CHD include increasing levels of high-

density lipoprotein cholesterol, decreasing levels of low-density lipoprotein cholesterol, prevention of clot formation, reduction in platelet aggregation, and lowering of plasma apolipoprotein A concentration, resulting in the attenuation of the formation of atheroma and decreasing the rate of blood coagulation.[134,135] It is possible, however, that how a person drinks alcoholic beverages matters as well. For example, wines are ingested more slowly because they are typically consumed in moderate amounts with food. Binge drinking of any type of beverage, however, increases the risk of mortality from CHD in particular.[131]

Pharmacokinetics and Pharmacology

When consumed in amounts typical of normal social drinking, the absorption of ethanol from the stomach, small intestine, and colon is complete; however, the rate is variable. Peak blood ethanol concentrations after oral doses in fasting subjects generally are reached in 30 to 75 minutes, but several factors can influence the rate and extent of absorption.[136] The most rapidly absorbed formulations are carbonated beverages containing 10% to 30% ethanol. In contrast, high concentrations of alcohol can produce vasoconstriction in the GI mucosa, which results in slowed or even incomplete absorption of ethanol. Absorption of ethanol from the small intestine appears to be more rapid than from any other part of the GI tract, and does not depend on the presence or absence of food. Factors that control the rate of gastric emptying significantly control the rate of absorption by controlling the rate at which ethanol is delivered to the small intestine.[137,138] For example, food in the stomach slows the absorption of ethanol, probably by slowing gastric emptying. The level of intoxication achieved is not solely related to the plasma concentration. For any particular plasma concentration, greater cognitive impairment is seen during times when the plasma level is rising compared with when ethanol is primarily being eliminated. The degree of intoxication also appears to be directly related to the rate at which pharmacologically active plasma

concentrations are attained. Alcohol negatively affects cognitive performance and has a differential effect on the descending versus ascending limb of the blood alcohol concentration (BAC) curve. The latter finding may have important ramifications relating to the detrimental consequences of alcohol intoxication.[139]

The blood alcohol level (BAL) or BAC is calculated using the weight of ethanol in milligrams and the volume of blood in deciliters. This yields a BAC expressed as a proportion (ie, 100 mg/dL or 1.0 g/L) or as a percentage (ie, 0.10% alcohol). Ethanol concentrations are usually converted to equivalent BACs for standardization purposes when measured in other body fluids.

The alcohol dehydrogenase (ADH) pathway is the major enzyme system responsible for alcohol metabolism in humans. The main alcohol metabolism occurs with ADH isoenzymes, in the stomach (ADH6 and ADH7) and in the liver (ADH1, ADH2, and ADH3). The pathway involves conversion of ethanol to acetaldehyde by these ADH isoenzymes, resulting in the reduction of nicotinamide adenine dinucleotide (NAD) to nicotinamide adenine dinucleotide hydrogen (NADH). In the second step, acetaldehyde is converted to acetate via the enzyme aldehyde dehydrogenase, which also reduces NAD to NADH. These are the rate-limiting steps in ethanol metabolism, and this route becomes saturated when large amounts of ethanol deplete NAD.[140] Acetate ultimately is converted to carbon dioxide and water. An additional pathway that is more involved in alcohol-dependent individuals than in those who are not involves the catalase pathway of peroxisomes and the microsomal ethanol oxidizing system (MEOS), in the smooth endoplasmic reticulum. The main functional component of the MEOS is the CYP2E1 enzyme.

Of a dose of ethanol, 90% to 98% is oxidized in the liver, with the remaining drug excreted unchanged in the alveolar air and urine. Ethanol metabolism formerly was described by zero-order kinetics; however, Michaelis–Menten and other nonlinear, concentration-dependent models are more accurate.[141,142] In some situations, a portion of the absorbed dose of ethanol does not appear to enter the systemic circulation, suggesting first-pass metabolism. However, the relative contribution of hepatic versus gastric ADH to this response

continues to be debated.[143,144] Using a two-compartment, Michaelis–Menten pharmacokinetic model and experimental data, it appears that gastric metabolism contributes negligibly to first-pass metabolism.[145–147] They believe that gastric metabolism accounts for sex and ethnic differences in first-pass metabolism. Estimates of total gastric ADH suggest that the enzyme can metabolize 0.9 to 1.8 g/hour of ethanol, depending on the concentration of ethanol consumed.[148] The extent of first-pass extraction tends to decrease as the dose of alcohol increases. This is likely because of saturation of ADH, regardless of the source. When plasma ethanol levels are >0.2 g/mL, the ADH system becomes saturated. As hepatic ADH becomes saturated, there is increased unchanged excretion of alcohol. This results in a more intense odor of alcohol on the breath as the plasma ethanol concentration increases. The metabolism of alcohol also then tends to become nonlinear because of stimulation of CYP2E1, which produces metabolic tolerance to ethanol in chronic users.

Lower first-pass metabolism has been found in alcohol-dependent individuals, females, the elderly, and Japanese subjects.[145,147] Gastric ADH may also play a role in the effect of food in reducing ethanol bioavailability. Food, by delaying gastric emptying, allows for more extensive gastric metabolism.[148]

The accepted average rate of ethanol oxidation is 0.15 g/mL/hour for males and 0.18 g/mL/hour for females.[149] Although this rate still is widely used for both legal and medical purposes, other data suggest wide variability in ethanol metabolism. For example, wide differences in ADH activity have been demonstrated and attributed to heredity and other causes.[150,151] Chronic heavy drinkers frequently oxidize ethanol at twice the normal rates, with their metabolic rates returning to baseline after a period of abstinence.[152] The rate of oxidation in chronic heavy drinkers may also increase with elevated blood ethanol levels.[152] In contrast, patients with end-stage liver disease may progress to the point at which they have almost no metabolic capacity.

Chronic alcohol use is associated with characteristic changes in the liver. Hyperlipidemia and fat deposition in the liver occur because

of shunting of the excess hydrogen into fatty acid synthesis and direct oxidation of ethanol for energy instead of body fat stores being used for energy. Fatty liver is the first step in a sequence of events that ultimately leads to alcoholic cirrhosis. Accumulated acetaldehyde, which interferes with mitochondrial function by shortening and thickening microtubules, has been implicated as playing a role in the hepatotoxic process. The damaged microtubules then inhibit the secretory functions of the hepatocytes, which results in an increase in size and weight of the liver.[153] Nutritional deficits and impaired hepatic protein metabolism may contribute as mechanisms of hepatotoxicity in chronic ethanol consumers.[154,155]

Acetaldehyde is believed to play a role in most actions of alcohol.[156] Elevated acetaldehyde concentrations during ethanol intoxication cause the commonly seen sensitivity reactions, including vasodilatation and facial flushing, increased skin temperature, increased heart and respiration rates, and lowered blood pressure. Acetaldehyde also contributes to the sensations of dry mouth and throat associated with bronchoconstriction and allergic-type reactions, as well as nausea and headache. These adverse effects mediated by acetaldehyde have the potential to protect drinkers against the excessive ingestion of alcohol, but acetaldehyde also has the potential to produce euphoric effects that may reinforce alcohol consumption. Acetaldehyde also contributes to the increased incidence of GI and upper airway cancers that are seen with increased incidence in heavy consumers of alcohol and which may also play a role in the pathogenesis of liver cirrhosis.[157] In addition, alcohol consumption is considered a major causative factor in the development of both acute and chronic pancreatitis.[158]

Chronic alcohol use may lead to neurologic conditions, such as neuropathies and dementia. These complications are caused by alcohol toxicity on the nerve cells and indirect effects related to malnutrition and head injuries.[159–161] Brain atrophy of gray and white matter, cerebellum, and amygdala has consistently been measured in those with chronic heavy alcohol intake.[162] The prevalence of dementia is five times higher in older adult patients with AUD than in those without.[163] Cognitive effects include worsening memory,

learning, and motor function related to both current alcohol use and a history of chronic use.[159]

Ethanol ingestion can depress the CNS through all the different stages of anesthesia. Tolerance to this effect occurs after chronic use such that a blood ethanol level of 0.150 g/mL will not produce apparent behavioral or neurologic dysfunction in persons who drink a pint or more of 80-proof liquor (or its equivalent) daily for several years.

Neurobiologic Basis of Alcohol Dependence

Proteins that are particularly sensitive to alcohol include ion channels, neurotransmitter receptors, and enzymes involved in signal transduction. Notable neurotransmitters, hormones, and neuropeptides (NPs) include adenosine, cannabinoid receptors, corticotropin-releasing factor (CRF), DA, GABA, ghrelin, glutamate, neurokinin-1 (NK1), neuropeptide Y (NPY), norepinephrine, opioid peptides, and serotonin (5-HT). The key inhibitory neurotransmitter in the CNS is GABA, which is associated with a chloride ion channel that is affected by low concentrations of alcohol. Normally, when GABA binds to the $GABA_A$ receptor, the chloride channel opens, allowing negatively charged chloride ions to enter the cell and inhibiting neuronal cell activity. In the presence of alcohol, GABA release accentuates the anxiolytic effect of both combined.[164] Receptor compensation for continual inhibition by alcohol is to reduce $GABA_A$ receptor subunits.[165] Other sedative medications, such as benzodiazepines, also bind to the chloride channel at slightly different sites and facilitate GABA inhibition. The existence of a common receptor mechanism for the actions of alcohol and sedative-hypnotics accounts for the cross-tolerance between these substances.

Glutamate is the major excitatory neurotransmitter in the CNS. Low doses of alcohol strongly inhibit NMDA receptors and inhibit neuronal activity.[166] After continual exposure to high doses of alcohol, NMDA receptors upregulate in an attempt to balance

alcohol's inhibitory action. Thus, the combined effect of alcohol on $GABA_A$ and glutamate is to inhibit excitation and facilitate sedation.

Alcohol also affects several other ion channels and receptors. The $5\text{-}HT_3$ receptor subtype is particularly sensitive to the action of low doses of alcohol and may result in activation of 5-HT and DA. Alcohol also modifies the activity of β-adrenergic and adenosine neurotransmitter receptors linked to adenylate cyclase through membrane-bound G-proteins. Low doses of alcohol can facilitate the activity of norepinephrine, 5-HT, DA, endocannabinoid signaling system, and other neurotransmitter receptors linked to G-proteins.[167–169]

On a neurobiologic behavioral level, the mesolimbic dopaminergic pathway from the ventral tegmental area to the nucleus accumbens is activated by most dependence-producing drugs, including alcohol, cocaine, opiates, and nicotine.[170,171] Putatively, activation of this pathway mediates drug reward, and is responsible for the dependence-producing properties of all drugs of abuse.[172] Repeated alcohol use sensitizes the system, so that behavioral stimuli associated with alcohol also begin to release DA and to facilitate additional alcohol use.[173] DA released by drugs of abuse are 2- to 10-fold that of natural rewards.[174] This sensitization may account for the craving and preoccupation with drugs of abuse.

Cessation of chronic alcohol use results in a withdrawal state of nervous system excitation that is dysphoric and negatively reinforcing. It has been suggested that abstinence contributes to alcohol craving and the preoccupation with alcohol use, in that dependent individuals will continue alcohol use to avoid this state.[175] As noted, chronic alcohol use causes $GABA_A$ downregulation and NMDA upregulation, leading to CNS hyperactivity. The locus coeruleus, a nucleus of norepinephrine-containing cells in the pons, becomes hyperactive during withdrawal, and is proposed as mediating some of the negative effects of withdrawal. Chronic alcohol and drug use alters gene expression and increases levels of adenylyl cyclase, upregulates cyclic adenosine monophosphate (cAMP)-dependent protein kinases, and activates cAMP-response

element binding protein (CREB) and several phosphoproteins in this brain region, mediating tolerance and dependence.[176]

ALCOHOL TOXICITY

Toxicology

In the medulla, ethanol can depress respirations by inhibiting the passive neuronal flux of sodium via a mechanism similar to that of general anesthetic agents.[177] The enzyme Na^+/K^+-adenosine triphosphatase (ATPase) is inhibited, cAMP concentrations are reduced, and GABA synthesis is impaired. Ethanol is a CNS depressant, and even the uninhibited behavior associated with its use is caused by preferential suppression of inhibitory neurons. More global neuronal inhibition is seen at high ethanol concentrations.

Treatment of alcohol intoxication is essentially supportive. In highly intoxicated patients, however, the prolonged slowing of the respiratory rate can lead to arrhythmias, cardiac arrest, and death, often accompanied by aspiration of vomitus. Respiratory depression is responsible for the respiratory acidosis acid–base abnormality. Even when blood ethanol levels are below those associated with medullary paralysis, a blunted respiratory response to hypercapnia and hypoxia is seen.[178,179] This makes the assessment of respiratory status a primary concern in severely intoxicated patients.

Highly intoxicated patients with depressed respiration require immediate supportive care that may include endotracheal intubation for respiratory support. This should be sufficient to restore acid–base balance to within normal limits. When metabolic acidosis is a significant component of the acid–base disturbance, it may be necessary to administer sodium bicarbonate. This should be done only in conjunction with appropriate respiratory support to prevent the development of hypercapnia.

Serum Ethanol Concentration

Chronic use of alcohol can produce significant tolerance; therefore, the BAL cannot be used as a sole determinant of physiologic status. By contrast, for the alcohol naive, a BAC in the 0.30 mg% range can be fatal, although chronic drinkers can be awake and alert at even higher levels. The blood ethanol concentration generally correlates with the clinical presentation of the patient (**Table 90-4**), but tolerance varies among individuals. Impairment in motor function may become observable at levels of 0.05 mg%. Moderate motor impairment usually is seen at 0.08 mg%, which is the legal definition of intoxication in all states when driving. Respiratory depression may occur with ethanol concentrations 0.45 mg%.[180] The accepted median lethal dose (LD_{50}) for ethanol in humans is a blood concentration of 0.50 mg%, although fatalities have been reported with ethanol concentrations ranging from 0.295 to 0.699 mg%.[181,182]

Table 90-4
Relationship of Blood Alcohol Concentration to Clinical Status

Blood Ethanol Concentration	Clinical Presentation[a]
50 mg/dL (0.05 mg%)	Motor function impairment observable
80 mg/dL (0.08 mg%)	Moderate impairment; legal definition of intoxication in all states when driving
450 mg/dL (0.45 mg%)	Respiratory depression
500 mg/dL (0.50 mg%)	LD_{50} for ethanol

LD_{50}, median lethal dose.

[a]Tolerance to alcohol varies among individuals.

Factors that may be associated with fatalities at lower ethanol concentrations include lack of tolerance to alcohol, ingestion of other drugs, heart disease, and pulmonary aspiration. For example, patients who died of combined ethanol and barbiturate ingestions had a mean ethanol concentration of only 0.359 mg%, a mechanism that is applicable to other more commonly used drugs that also

depress respiration such as anxiolytics and opioids.[182] Therefore, the clinician should order a toxicologic urine screen to rule out possible concurrent drug ingestion.

Acute Management

In the alert intoxicated patient, general management is supportive and protective. Volume depletion resulting in hypotension often occurs in ethanol-intoxicated patients. Hypothermia also is a complication of severe intoxication and can contribute to hypotension. Hypoglycemia most often occurs in conjunction with reduced carbohydrate intake. This situation is common in malnourished alcoholics, but also might be particularly pronounced if a patient was dieting. If IV fluids are given, thiamine administration should precede that of glucose to prevent Wernicke encephalopathy. Administration of a short-acting benzodiazepine, such as lorazepam, should be considered.

Gastric lavage may be useful if ingestion of other drugs is expected, or when the large consumption of alcohol is very recent. Activated charcoal absorbs ethanol poorly, but should be administered when coingestion of other drugs is suspected. Hemodialysis rapidly removes ethanol from the body.[183] In uncomplicated cases, it has been suggested that dialysis be initiated immediately when the blood ethanol concentration is >0.6 mg%.[181] Ventilatory assistance and good supportive care usually are most important because respiratory depression is the primary cause of death in ethanol intoxication. With good supportive care, dialysis is generally unnecessary. Dialysis may be considered if the patient cannot be stabilized or has other complicating factors, such as coexisting disease states (eg, renal dysfunction) or ingestion of other drugs (**Table 90-5**).

Table 90-5

Acute Alcohol Intoxication: Symptoms and Treatment

Symptom	Course	Treatment

Symptom	Course	Treatment
Respiratory acidosis	Alcohol-induced respiratory depression; blunted response to hypercapnia and hypoxia	Endotracheal intubation for respiratory support
Coma	Alcohol-induced CNS depression; ingestion of other drugs	Gastric lavage, naloxone (Narcan®) 1 mg, repeat every 2–3 minutes up to 10 doses, depending on response and suspicion of ingestion. Dialysis possible
Hypotension	Hypovolemia	IV fluid replacement
Hypoglycemia	Most often occurs in malnourished patients. Pyruvate is converted to lactate, rather than to glucose, through gluconeogenesis	50% glucose (50 mL) by IV push

CNS, central nervous system; IV, intravenous.

ALCOHOL WITHDRAWAL

CASE 90-10

QUESTION 1: J.M. is a chef at a nursing home where his wife is the administrator. He drinks at work and was found unconscious and brought to the hospital. His wife states that J.M. regularly drinks half a gallon of vodka daily and has suffered an alcohol withdrawal seizure in the past. J.M.'s wife states that she does not believe that he ever abused street or prescription drugs. His BAC on admission was 0.52 mg%. J.M. has a history of hepatic insufficiency secondary to cirrhosis. The following laboratory results are reported:

Sodium, 143 mEq/L	Albumin, 4.7 g/dL
Potassium, 4.2 mEq/L	Cholesterol, 423 mg/dL
CO_2, 25.2 mEq/L	Creatinine kinase (CK), 1344 units/L
Chloride, 107 mEq/L	Total bilirubin, 2.3 mg/dL
Blood urea nitrogen (BUN), 18	Direct bilirubin, 0.3 mg/dL

mg/dL	
Creatinine, 0.8 mg/dL	Alkaline phosphatase (ALP), 74 units/L
Glucose, 101 mg/dL	Aspartate transaminase (AST), 288 units/L
Calcium, 9.9 mg/dL	Alanine transaminase (ALT), 148 units/L
Magnesium, 0.9 mg/dL	γ-Glutamyl transpeptidase (GGT), 992 units/L
Uric acid, 6.3 mg/dL	

What signs and symptoms evident in a clinical diagnosis of alcohol withdrawal need to be monitored in J.M.?

For many alcohol-dependent individuals with significant physical dependence, a cluster of withdrawal symptoms known as *alcohol withdrawal syndrome* (AWS) may occur on cessation or reduction of alcohol consumption. Depending directly on the degree of physical dependence, AWS can range from creating significant discomfort to mild tremor to alcohol withdrawal-related delirium, hallucinosis, seizures, and, potentially, death.[184,185] A GGT of 992 units/L in combination with the patient's medical history suggests that J.M. is a heavy drinker. Although J.M.'s AST, ALT, and total bilirubin levels are elevated, his direct (unconjugated) bilirubin is within normal limits, suggesting a problem with bilirubin excretion as would be consistent with viral hepatitis or cirrhosis.

Patients may present with AWS in a variety of settings because alcohol-dependent patients may be unrecognized and experience withdrawal after inpatient hospital admission for unrelated medical reasons. For example, a sample from a primary care practice indicated that 15% of patients presented with at-risk drinking patterns or identified alcohol-related problems.[186] Surgical patients should be screened preoperatively for possible alcohol dependence, to prevent and adequately treat AWS-related complications during and after surgery.[187]

Diagnosis requires cessation or reduction in alcohol use that has been heavy and prolonged, and two or more of the following

symptoms developing within several hours to a few days of the cessation: autonomic hyperactivity, hand tremor, insomnia, nausea or vomiting, transient hallucinations or illusions (tactile, visual, or auditory), psychomotor agitation, anxiety, and generalized tonic–clonic seizures.[1] These symptoms must cause significant distress or impairment of important areas of functioning, and not be caused by a general medical condition or another mental disorder. Withdrawal-related seizure is considered a more severe manifestation of withdrawal, as is alcohol withdrawal delirium (AWD), or *delirium tremens* as it is traditionally called. AWD is estimated to have a mortality rate of ~5% of patients who go into alcohol withdrawal.[188] Recognized predictors for AWS complications include the duration of alcohol consumption, total number of prior detoxifications from alcohol, and previous withdrawal-related seizures and episodes of AWD.[189]

Case 90-10, Question 2: How could the severity of J.M.'s withdrawal symptoms be quantitatively assessed?

Of currently used instruments available for measuring the degree of withdrawal in an alcohol-dependent patient, the most commonly used is the revised Clinical Institute Withdrawal Assessment for Alcohol–Revised (CIWA-Ar).[190] In addition, the Sedation-Agitation Scale (SAS) could be used to assess agitation.[191] The CIWA-Ar is a validated 10-item scale used for grading severity of AWS that is often used as an inpatient assessment of withdrawal. The CIWA-Ar provides a final score with a maximum of 67 points assessing the extent of headache, nausea, tremors, agitation, paresthesia, sweats, audio and visual disturbances, and lack of awareness of time or location. Treatment of AWS can be initiated based on a patient's CIWA-Ar score. A CIWA-Ar rating of ≤8 points represents mild withdrawal and needs little pharmacologic support. A rating of 9 to 15 is associated with moderate withdrawal and may require some pharmacotherapy. A rating >15 corresponds to severe withdrawal, with an increased risk of seizures and AWD. Providers should also

consider concomitant illnesses and medications when interpreting CIWA-Ar scores because individual items in the scale are not specific to AWS, and likewise some manifestations of withdrawal may be blunted. The SAS can be used in combination with the CIWA-Ar to evaluate the level of agitation and consciousness of a patient, and be linked to administer benzodiazepines on a symptom-triggered regimen when a patient becomes agitated (for scores >4 on a 7-point scale).

Management of Withdrawal

Case 90-10, Question 3: What drugs are demonstrated to be the most clinically effective for alcohol withdrawal, particularly in a patient such as J.M. with evidence of cirrhosis?

Benzodiazepines

Benzodiazepines modulate anxiolysis by stimulating $GABA_A$ receptors and, in doing so, substitute pharmacologically for alcohol.[192] They are considered the drugs of choice for alcohol withdrawal,[187,192,193] long-acting benzodiazepines (eg, chlordiazepoxide and diazepam) and short-acting agents (eg, lorazepam and oxazepam) represent the most efficacious pharmacotherapies for the treatment of acute alcohol withdrawal.[186] They are effective in preventing both first seizures and subsequent seizures during alcohol withdrawal.[194] Longer acting benzodiazepines may provide for easier weaning because they gradually self-taper on metabolism and excretion; this allows for less fluctuation in plasma drug levels.[195] Longer acting benzodiazepines also cause fewer rebound effects and withdrawal seizures on discontinuation. Shorter acting agents (eg, lorazepam or oxazepam), which undergo phase II hepatic metabolism to inactive metabolites, require more frequent dosing, but may be more appropriate for alcoholics with liver disease and the elderly.[193,196] When used

appropriately, all benzodiazepines appear equally effective in ameliorating the signs and symptoms of alcohol withdrawal; however, the choice of a benzodiazepine is dependent on factors such as pharmacokinetic properties, dosage formulation, presence of liver impairment, and ease of dosage titration[197] (**Table 90-6**).

Table 90-6
Suggested Treatment Strategies for Alcohol Withdrawal Syndrome

Protocol	Clinical Rationale	Drug	Dosing Regimen (Example)	Considerations
Fixed-Schedule Regimen	The patient receives a fixed dose of medication for 2–3 days regardless of the severity of symptoms. This approach is generally used in severe alcohol withdrawal.	Chlordiazepoxide	25–100 mg PO every 2–6 hours or 25 mg IV every 2–4 hours	Protocol fixed dose and time parameters are decided beforehand. Additional medication is provided as needed when symptoms are not controlled (eg, the CIWA-Ar score remains at least 8–10).
		Diazepam	10 mg PO every 1–2 hours (maximum 60 mg) or 5–10 mg IV 20–120 minutes (maximum 100 mg/hour or 250 mg/8 hour)	
		Lorazepam	On days 1 and 2, give 2–4 mg PO four times a day. On days 3 and 4, give 1–2 mg PO four times a day. On day 5, give 1 mg PO twice a day. May use IV or IM (maximum 20 mg/hour or 50 mg/8 hour)	
Symptom-Triggered Regimen	The patient is assessed every hour using the CIWA-Ar to determine the need for medication. The primary advantage of this approach is that less medication is used to achieve the same control and less sedation.	Chlordiazepoxide	50–100 mg	Less abuse potential for outpatients, low cost; long acting 24–48 hours
		Diazepam	10–20 mg	Long duration of action (20–50 hours), which provides a smooth treatment course with less breakthrough symptoms
		Lorazepam	2–4 mg	Shorter duration of action may be more appropriate for patients at risk for prolonged sedation (eg, elderly, hepatic impairment).
Alternative Therapies	In patients with benzodiazepine allergy or when use of a benzodiazepine is deemed medically inappropriate	Carbamazepine	Taper from 600–800 mg on day 1 down to 200 mg over 5 days. 400 mg PO tid for 3 days, then 400 mg PO bid for 1 day, then 400 mg PO for 1 day	Both carbamazepine and baclofen are nonaddicting. Few drug interactions Cause relatively little cognitive impairment
	May be equally efficacious as are benzodiazepines	Baclofen	5 mg PO tid for 3 days and then increase to 10 mg tid	Known to lower the seizure threshold; more information is needed before its routine use in alcohol withdrawal.
Adjunctive Therapies	Adrenergic hyperactivity	Clonidine	0.1 mg PO bid as needed	For mild-to-moderate hyperactivity
	Adrenergic hyperactivity	β-Blockers: Atenolol Metoprolol	50 mg PO daily 2.5–5 mg IV	May improve vital signs faster than does oxazepam alone. Up to 3 doses about 2 minutes apart; use parameters for HR and blood pressure.
	Agitation, hallucinations, delirium	Neuroleptics: Haloperidol Olanzapine	0.5–5 mg PO/IM/IV every hour; maximal dose 100 mg/day 10 mg IM	Rapid onset, but note QTc prolongation (eg, >450 ms); recommend baseline ECG before using IV. Maximal dosing, three 10-mg doses given 2–4 hours apart; monitor for orthostatic hypotension before the administration of repeated doses.

bid, two times daily; CIWA-Ar, Clinical Institute Withdrawal Assessment for Alcohol–Revised; ECG, electrocardiogram; HR, heart rate; IM, intramuscular; IV, intravenous; PO, orally; tid, three times daily.

DOSE

Two strategies for dosing benzodiazepines in AWS include fixed-schedule and symptom-triggered regimens. Fixed-schedule regimens involve a set dose and interval for the agent chosen, which is to be tapered off at specific times, usually starting on the second day of treatment. Symptom-triggered regimens depend on the use of a rating scale of withdrawal severity, such as the CIWA-Ar previously noted, which is repeated at set intervals. Medication is only administered if the scoring from the scale is above a predetermined threshold value for treatment. In this way, the risk of undermedicating or overmedicating patients may be minimized, because the degree of withdrawal symptoms guides dosing. Several studies confirm that symptom-triggered regimens compared with fixed-dose regimens appear to result in a shorter duration of necessary therapy and less medication administered in total without any loss of efficacy.[197]

The treatment challenge associated with individuals who are in alcohol withdrawal with a comorbid medical illness is illustrated by the case of a patient with AWS who has coronary artery disease. Such a patient may be more aggressively treated for withdrawal-related hypertension and thus treated with a β-blocker or clonidine. The result of such adjuvant treatment may be a reduced sensitivity of the CIWA-Ar owing to a masking of the patient's autonomic manifestations of withdrawal. This could then lead to a higher likelihood of undermedicating the patient for withdrawal and may put the patient at higher risk for severe sequelae from withdrawal. Because of these exclusion criteria, the symptom-triggered approach has not been tested in such populations or those with histories of severe withdrawal including seizures or delirium. Therefore, traditional fixed-dose regimens are recommended in these populations.[197] An effective approach is most likely to consider combining these two dosing strategies. For example, a low-risk patient (no history of AWS or AWD, the patient consumes low weekly amounts of alcohol and has no signs or symptoms of early AWS) receives a symptom-triggered regimen (eg, lorazepam 1 mg every hour as needed). Alternatively, a high-risk patient (history of AWS, AWD, or withdrawal seizures, consumes large daily amounts of alcohol, has signs or symptoms of early AWS) receives fixed-dose

lorazepam or diazepam with a tapering dose schedule and as-needed benzodiazepine administration for uncontrolled alcohol withdrawal signs or symptoms. Importantly, phenobarbital, dexmedetomidine, and propofol are useful adjuncts to benzodiazepines if an inpatient has severe symptoms.[197]

CONTRAINDICATIONS, WARNINGS, AND INTERACTIONS

Elderly patients, those with hepatic or renal insufficiency, and those with medical (eg, diabetes, cirrhosis) or other psychiatric illnesses (eg, dementia) require close observation. As noted earlier, in patients receiving calcium channel blockers, β-blockers, and α_2-adrenergic agonists, some signs of withdrawal such as hypertension, tachycardia, and tremor may not be apparent. In addition, patients with dementia are more difficult to assess for progression to delirium tremens. The benzodiazepines' adverse effect of cognitive impairment is more difficult to assess in a patient with baseline dementia. As in middle-aged adults, the CIWA-Ar is used for symptom-triggered dosing protocols in the older adult population. However, dosage requirements are significantly lower than they are for younger adults.[198]

Patients with a history of severe withdrawal symptoms, withdrawal seizures, or delirium tremens; multiple previous detoxifications; concomitant psychiatric or medical illness; recent high levels of alcohol consumption; pregnancy; and lack of a reliable support network should be considered for inpatient treatment regardless of the severity of their symptoms.[197]

Lorazepam is the only benzodiazepine with predictable IM absorption (if IM administration is necessary). Rarely, it is necessary to use extremely high dosages of benzodiazepines to control the symptoms of alcohol withdrawal. Controlled studies comparing the advantages and disadvantages of the various benzodiazepines in alcohol detoxification have not been performed, and no evidence exists to definitively support the use of lorazepam as the first-line agent in the treatment of AWS.[197,199]

In most patients with mild-to-moderate withdrawal symptoms, outpatient detoxification is safe and effective, and costs less than does inpatient treatment. If outpatient treatment is chosen, the patient and support person(s) should be instructed on how to take the prescribed medication, its side effects, the expected withdrawal symptoms, and what to do if symptoms worsen. Small quantities of the withdrawal medication, especially benzodiazepines, should be prescribed at each visit. Because close monitoring is not available in outpatient treatment, a fixed-schedule regimen should be used. The addition of phenobarbital for withdrawal symptoms as either a loading dose or throughout treatment has been beneficial for intensive care unit (ICU) stays and the amount of lorazepam used; however, the risk of respiratory depression and drug interactions is significantly higher when phenobarbital is combined with benzodiazepines. Early introduction of phenobarbital is associated with a reduced likelihood of transfer to the ICU.[200,201]

Given J.M.'s elevated liver enzymes, a reasonable approach would be to start with lorazepam. Shorter acting agents, such as lorazepam, which do not undergo extensive hepatic metabolism, are more appropriate for patients with evidence of hepatic insufficiency.

ADJUNCTIVE TREATMENTS

CASE 90-10, QUESTION 4: What adjunctive therapeutic support might be considered for J.M.?

The hydration, electrolyte (especially potassium and magnesium), and nutritional status of patients should be assessed at presentation. Support with IV fluids may be necessary in those patients with excessive losses through vomiting, sweating, and hyperthermia.[202] Thiamine and multivitamins as well as folate 1 mg should be routinely administered to patients in alcohol withdrawal. If IV fluids are given, to prevent precipitation of Wernicke encephalopathy,

thiamine administration should precede that of glucose.[189] Alcohol-dependent patients are deficient of thiamine and have a higher risk of developing Wernicke encephalopathy.[203] The condition is a triad of acute mental confusion, ataxia, and ophthalmoplegia. Korsakoff amnestic syndrome is a late neuropsychiatric manifestation of Wernicke encephalopathy with memory loss and confabulation; hence, the condition is referred to as *Wernicke–Korsakoff syndrome*. It is most often seen in chronic patients with AUD, but it can also be seen in disorders associated with malnutrition, for example, long-term hemodialysis or patients with acquired immunodeficiency syndrome (AIDS).[204]

Thiamine deficiency results in a decrease in cerebral glucose utilization. The body usually stores about 3 weeks of thiamine, with daily requirements of about 1.5 mg. Rapid correction of brain thiamine deficiency can occur with high plasma concentrations of thiamine, achieved by parenteral supplementation only because absorption of the oral thiamine by the GI tract is minimal (>5%), even with massive oral daily dosing.[203] Patients should receive at least 200 to 500 mg tid IV for 3 days to prevent the neuropsychiatric effects of thiamine deficiency.[204]

Several adjunctive medications, aside from the sedative-hypnotics, may serve ancillary roles in the therapy of AWS. Their selection should be based on treating specific symptoms associated with the syndrome. For instance, β-blockers (propranolol,[205] atenolol[206] or α_2-adrenergic agonists [eg, clonidine[207] or dexmedetomidine] if in an ICU) can be used for moderate-to-severe hypertension or other autonomic manifestations. α_2-Adrenergic agonists are preferred because it reduces NE outflow from the nerve and addresses all hyperadrenergic effects instead of just effecting the β-receptors with a β-blocker, and delirium seems to be more common with the β-blocker use.[197,199] Antipsychotics (eg, haloperidol and quetiapine) can be used for managing hallucinations and severe agitation, but care must be taken because these drugs can reduce the seizure threshold.[192,197,208]

PHARMACOTHERAPY OF ALCOHOL DEPENDENCE

CASE 90-11

QUESTION 1: R.M. is a 55-year-old male, weighing 140 pounds (63.50 kg), who used to have about 60 drinks a week before going through alcohol detoxification. R.M. is married and has a good job, and he is now committed to remain alcohol abstinent. R.M. heard about a drug called disulfiram from a friend and is interested in using this medication to help him abstain from drinking. Laboratory values obtained today include the following:

Sodium, 132 mEq/L	AST, 30 units/L
Potassium, 3.3 mEq/L	ALT, 35 units/L
CO_2, 22.6 mEq/mL	Uric acid, 9.1 mg/dL
Chloride, 109 mEq/L	Calcium, 8.7 mg/dL
BUN, 14 mg/dL	Magnesium, 1.7 mg/dL
Creatinine, 1.0 mg/dL	Albumin, 4.0 g/dL
Glucose, 123 mg/dL	Cholesterol, 255 mg/dL
Total bilirubin, 0.3 mg/dL	CK, 78 units/L
Direct bilirubin, 0.1 mg/dL	GGT, 30 units/L
ALP, 53 units/L	

Is disulfiram an appropriate agent to consider for R.M.?

To assess AUD, treatment requires an accurate medical history, including laboratory test results. In addition, several instruments are available to screen and delineate the extent of a patient's alcohol use. Ultimately, time and purpose for use are always major factors when deciding which instrument to use. The simplest screen to assess risk of alcohol abuse is to ask the patient the following question: During the past year, on how many occasions have you had five or more drinks (for a male) or four or more drinks (for a

female) at one time?[209] An affirmative answer would suggest that further follow-up of the patient's alcohol use history is needed. A second tool called the **C-A-G-E** consists of four questions: (1) Have you ever felt you should *c*ut down on your drinking? (2) Have people *a*nnoyed you by criticizing your drinking?; (3) Have you ever felt bad or *g*uilty about your drinking?; and (4) Have you ever felt you needed a drink first thing in the morning to steady your nerves or get rid of a hangover (*e*ye opener)? Positive responses to two questions suggest an alcohol problem (**Table 90-7**).[210] The Alcohol Use Disorders Identification Test (AUDIT), which was developed by the World Health Organization, has also been shown to be effective in screening individuals and distinguishing problem drinkers from others.[211]

Table 90-7
Useful Screens for Assessing Alcohol Problems

The C-A-G-E Screening Questions (CAGE)
Have you ever felt you should *c*ut down on your drinking?
Have other people *a*nnoyed you by criticizing your drinking?
Have you ever felt *g*uilty about drinking?
Have you ever taken a drink in the morning to calm your nerves or get rid of a hangover (*e*ye opener)?
Methods for Determining Recent Alcohol Consumption
Acute consumption ▪ Blood alcohol concentration ▪ Urine (ethyl glucuronide) ▪ Saliva ▪ Breath alcohol concentration
Recent heavy consumption ▪ γ-Glutamyl transferase (GGT) ▪ Carbohydrate-deficient transferrin (CDT) ▪ Mean corpuscular volume (MCV)

Pharmacotherapy

The pharmacologic treatments of alcohol dependence focus on relapse prevention once detoxification is complete and the patient has achieved a few days of abstinence. Treatment is intended to be an adjunct to psychosocial treatments and not used alone.[212] To date, disulfiram, acamprosate, and naltrexone tablet and injection have been FDA approved for the treatment of alcohol dependence. In addition, several other drugs, such as quetiapine and ondansetron, have shown varying degrees of success.[212–233] Yet, much is still unknown about the long-term rates of abstinence, how long these drugs should be used once patients are in treatment, the optimal doses, and whether the drugs are more effective in males or females or for which specific subpopulations.[234]

DISULFIRAM

Disulfiram is an irreversible acetaldehyde dehydrogenase inhibitor that blocks alcohol metabolism, leading to an accumulation of acetaldehyde. Disulfiram reinforces an individual's desire to stop drinking by providing a disincentive associated with increased acetaldehyde levels, resulting in headache, palpitations, hypotension, flushing, nausea, and vomiting when they consume alcohol. Severe reactions may result in arrhythmia, MI, and acute congestive heart failure. Because older adults potentially have cardiovascular conditions before starting disulfiram, the risk of use likely outweighs the benefit in the elderly.[235–237] The primary predictor of success with disulfiram is the patient's commitment to total abstinence from alcohol. Although anecdotal reports of success are common, clinical evidence suggests that disulfiram appears to be most effective for alcoholics who are involved in special high-risk situations (eg, weddings and graduations) and is particularly effective when administration is supervised.[3,212,238]

Controlled clinical trials of disulfiram have clearly shown efficacy, yet this has not been a consistent finding.[212] Double-blind, placebo-controlled studies using disulfiram are difficult because the

psychological deterrent to use alcohol is experienced by both treatment groups, and those who relapse will be unblinded when they experience the pharmacologic interaction.

In the most rigorous clinical trial conducted in a population of veterans, no significant difference in abstinence rates was demonstrated between patients taking placebo or 1 or 250 mg of disulfiram.[213] However, patients randomly assigned to receive 250 mg of disulfiram daily drank less frequently (significantly fewer drinking days per year). Patients who were middle-aged and had social stability were more likely to benefit from disulfiram. In another trial in which administration was supervised, patients receiving disulfiram drank less alcohol and less frequently; however, on randomization, patients were unblinded to their drug.[239]

The efficacy of disulfiram compared with acamprosate and naltrexone shows definitive efficacy advantage for disulfiram when the patients are assigned to supportive care that verifies adherence.[240,241] However, no advantage was seen for combining disulfiram with naltrexone in dually diagnosed alcohol-dependent patients.[242] In one study, disulfiram combined with acamprosate resulted in increased days of cumulative abstinence.[243]

Dosing

The recommended starting dose of disulfiram is 250 mg once daily, with a range of 125 to 500 mg/day.[242] If a patient drinks and does not experience a disulfiram–ethanol reaction, the dose can be increased to 500 mg, because a significant proportion of patients may not experience a disulfiram–alcohol reaction at the usual 250-mg daily dose.[244,245] Side effects are increased, however, at doses exceeding 250 mg. Dosing starts at least 12 to 24 hours after abstinence initiation (when the blood or breath alcohol concentration is zero). Treatment continues, depending on the particular needs of the individual, but is generally at least 90 days, and maintenance therapy may be required for years.

Contraindications, Warnings, and Interactions

Because of the intense cardiovascular and physical changes that occur in the disulfiram–ethanol interaction, disulfiram is contraindicated in patients with cardiac disease, coronary occlusion, cerebrovascular disease, and renal or hepatic failure. At somewhat higher doses, psychotic reactions have occurred. It is not definitive that disulfiram causes fetal abnormalities when administered during pregnancy, but some data are found regarding limb reduction anomalies in infants born to disulfiram-treated mothers taking disulfiram during the first trimester of pregnancy.[246,247] Thus, disulfiram should only be used during pregnancy if the expected benefit to the mother and fetus is greater than is the possible risk to the fetus; however, it should be avoided in the first trimester (category C). No information is available about the safety of this medicine during breast-feeding.

Disulfiram can also be hepatotoxic and should be used cautiously in patients with liver disease. Liver function should be established at baseline and after 14 days of treatment, and a complete blood count (CBC) and liver function tests (LFTs) should be obtained every 6 months.[248] A high AST/ALT ratio is more indicative of alcohol-induced liver toxicity, whereas disulfiram is more likely to have elevations in both ALT and AST.[249] A high bilirubin is a predictor of the need for liver transplantation or death from disulfiram.[249]

R.M. has normal hepatic function; however, LFTs should be monitored at baseline and periodically during treatment. Although not all clinicians agree, most would recommend—at minimum—baseline LFTs: ALT, AST, and GGT and withholding disulfiram when LFTs are more than three times the upper limits of normal.[248] If elevated, repeat LFTs every 1 to 2 weeks until normal, and then every 3 to 6 months if no elevations, with an awareness that increased LFT results may signal a return to drinking rather than to disulfiram toxicity.[250,251] Persistently elevated LFTs may also indicate viral hepatitis (B or C), for which alcoholics have a higher risk, and thus the need to order a hepatitis profile. Currently, guidelines point out that a reduction in alcohol use will lead to more normalized LFTs.

Psychiatric adverse effects include disorientation, agitation, depression, and behavioral changes such as paranoia, withdrawal and bizarre behaviors, and worsening of schizophrenia, especially at doses >250 mg daily.[252,253] Disulfiram should be avoided or used very cautiously in persons with these conditions, although it can be used safely at a dose of 250 mg daily in alcohol-dependent patients with concomitant psychiatric disorders, including schizophrenia.[242,254,255] Common side effects of disulfiram include drowsiness, particularly in the first few weeks of treatment, a metallic or garlic taste, and sexual dysfunction. The dose can be taken at bedtime if drowsiness or tiredness occurs.

Disulfiram is metabolized to some extent by stomach acids to diethyldithiocarbamic acid (DDC), which then converts to carbon disulfide and diethylamine. Disulfiram, DDC, and copper-chelated DDC are absorbed. The metabolism of disulfiram and its biotransformed absorbed metabolites is eventually affected by several enzymatic pathways, with 1% to 20% primarily excreted in the feces as unchanged disulfiram.[256,257] Disulfiram is also a mild inhibitor of CYP2E1 and CYP2C9,[256,257] and can interact with anticoagulants (warfarin), antiepileptics (phenytoin and carbamazepine), some benzodiazepines (diazepam), and tricyclic antidepressants (amitriptyline and desipramine), potentially increasing the toxicity of these medications. Delirium can result in combination with monoamine oxidase inhibitors. Adverse effects with disulfiram that mimic the alcohol–disulfiram interaction can also occur with metronidazole and omeprazole.[256–258]

To receive optimal results with disulfiram, patients must receive regular counseling and be closely monitored for any changes in hepatic function. Having someone participate in helping to validate the administration process is known to lead to better outcomes. Discontinuation of disulfiram should occur only after consultation with the prescriber and counselor involved. Patients must stop the medication for at least 3 days (up to 14 days in some) before being exposed to products containing alcohol. It is important to educate patients taking disulfiram about the dangers of consuming even small amounts of alcohol in foods, over-the-counter medications,

mouthwashes, and topical lotions. The patient should report any respiratory difficulty, nausea, vomiting, decreased appetite, dark-colored urine, or a change in pigmentation in the skin or eyes (primarily yellowing).

Summary

Generally, given the special circumstances needed for success, disulfiram is not the drug of choice for treating alcoholism. The social, medical, and psychiatric status of a candidate is an important consideration in the use of disulfiram. R.M. would appear to be a reasonable candidate for disulfiram given he has agreed to have his medication administration supervised (in this case, by his wife), his steady employment, and his motivation to sustain abstinence. R.M. should also receive counseling and support services on a regular basis.

ACAMPROSATE

Acamprosate (Campral®) has multiple actions but is principally a glutamate and GABA modulator. The key mechanism of action is considered to be a weak functional antagonist of the glutamate NMDA receptor, possibly mediated through indirect modulation of the receptor site via antagonism at the mGluR5 receptor.[259] It also has $GABA_B$ receptor agonism, but this effect would be minimal.[260,261] A series of meta-analyses and systematic reviews demonstrated that when used as an adjunct to psychosocial interventions, acamprosate improves drinking outcomes such as the length and rate of abstinence.[212,262,263] This effect is less likely if acamprosate is not initiated quickly after detoxification.[264,265] Evidence indicates that the effect of acamprosate on abstinence lasts after the treatment is stopped.[266] Acamprosate appears to be especially useful in a therapeutic regimen targeted at promoting abstinence, and can be

used in primary care settings as well as specialized addiction treatment programs.[267] Few contraindications to treatment exist. Little consistent information is found about patient characteristics that predict improvement while taking acamprosate. In a meta-analysis of all U.S. and European studies, predictors of abstinence were motivation, readiness to change, baseline abstinence, initial first week compliance, and living with a partner or child. A pooled analysis of seven European trials, however, found no significant predictors of the abstinence outcome measures.[268] Candidates for acamprosate should be committed to abstinence and begin the medication after being abstinent from alcohol.[269,270]

In a systematic review of the efficacy data related to acamprosate, proof of efficacy was strong.[269] Moreover, several studies on acamprosate have reported positive results. For example, in a study of 272 severely dependent alcoholics, patients receiving acamprosate showed a significantly higher continuous abstinence rate within the first 2 months of treatment compared with patients receiving placebo.[216] Of acamprosate-treated patients, 40% were continuously abstinent for a 48-week period compared with 17% of those who received placebo.

Acamprosate has also been studied for periods of up to a year. In a long-term follow-up (12 months) after trial completion, acamprosate still maintained an effect on abstinence rates, but not on nondrinking days. Some studies have found limited to no efficacy, although two of the studies may have been underpowered.[223,271–274] One of these studies also had a short treatment period, and the other had a long delay in initiating treatment.[272,273] In summary, most studies suggest that acamprosate is a safe and well-tolerated drug for the promotion of alcohol abstinence.[275]

Dose

Even though acamprosate has a half-life of 20 to 33 hours, the drug dosing for acamprosate is 666 mg orally three times daily. Studies with doses of 999 mg orally bid have found this dose to be

bioequivalent.[260,276,277] Patients can be started on the full dose without titration. Acamprosate is not well absorbed from the GI tract, and with a terminal half-life of around 30 hours, it takes several days to achieve desired blood levels of the medication.[278] The medication appears to be safe and effective in alcoholics, with minimal side effects. It does not appear to produce sedation, and does not cause drug dependence. Main adverse effects of acamprosate appear to be GI, including nausea, diarrhea, and bloating. Nausea or diarrhea can be easily managed, but if symptoms are severe or persistent, the dose should be reduced by one-third to one-half. The duration of therapy ultimately depends on treatment success and the willingness of the patient to continue therapy indefinitely.

Contraindications, Warnings, and Interactions

Therefore, patients with decreased renal function should receive lower doses. Patients with moderate-to-severe renal impairment had a 2- to 4-fold increase in plasma concentrations compared with patients with normal renal function.[260,279] For those with a creatinine clearance (CrCl) of 30 to 50 mL/minute/1.73 m^2, reducing the dose by one-half is recommended.[260,261] Because of acamprosate's near-complete elimination unchanged through the kidneys, dose adjustments are not necessary for liver function impairment.[277] Acamprosate should only be used during pregnancy when the benefit clearly outweighs the risk because the drug has been shown to be teratogenic (category C) in rats.[278] Tetracyclines may be inactivated by the calcium component in acamprosate during concurrent administration.[278] Naltrexone increases plasma levels of acamprosate, although the clinical significance of this interaction is unknown and the two can be safely used together.[278,280] Suicidal ideation and attempted and completed suicides have occurred in patients taking acamprosate.

Acamprosate must be used in combination with a psychosocial program such as CBT or at regular AA meetings. Acamprosate may be taken without regard to meals. The tablets should not be crushed

and should be taken whole. Although no interaction with alcohol occurs, abstinence in combination with counseling and social support is required to attain optimal treatment. Patients should report persistent diarrhea, sudden or excessive weight gain, swelling of the extremities, respiratory difficulties, fainting, or thoughts of suicide.

In a retrospective long-term study in 353 alcohol-dependent patients, supervised disulfiram was found to be superior to acamprosate, particularly in patients with a long history of alcohol dependence.[241]

NALTREXONE

Naltrexone is an opiate receptor antagonist that blocks the opiate stimulatory effects of alcohol to reduce the pleasure from drinking. However, the unpleasant sedating and GI effects of alcohol remain. This may help reduce the amount of alcohol ingested and eventually decrease the frequency of relapse.[237,261] Naltrexone's benefit is greater in individuals who drink for the reward or positive reinforcement felt from alcohol.[281,282] Naltrexone also decreases cravings for alcohol, as measured by subjective scales. This effect is better with naltrexone than with acamprosate.[283,284] Naltrexone also has a labeled indication for the treatment of opiate use disorder. As a result, patients with both AUD and opiate use disorder may benefit from this agent. Evidence seems to support the use of naltrexone as an adjunct to psychosocial interventions, with higher abstinence rates in short-term treatment, and as a deterrent to progressing from a lapse to a full-blown relapse.[212,244,284,285] Naltrexone is as efficacious as disulfiram and probably more efficacious than is acamprosate.[223,284,286,287]

Several studies indicate that naltrexone is most effective in patients with strong craving,[214,288] poor cognitive status at study entry,[289] and high compliance.[290,291] This observation is consistent with the demonstrated effect of naltrexone in reducing craving. Evidence also indicates that persons with a family history of

alcoholism, early age at onset of drinking, and comorbid use of other drugs are more likely to benefit from naltrexone.[292]

Comprehensive reviews of pharmacotherapies for alcoholism concluded that oral naltrexone produced a consistent decrease in the relapse rate to heavy drinking and in drinking frequency, although it did not enhance absolute abstinence rates.[270,293,294] More specifically, several studies using naltrexone report the opioid antagonist to be more effective than is placebo in reducing relapse rates, in increasing the percentage of nondrinking days,[214,215,290] and in reducing craving in heavy drinkers.[295] Yet, other studies fail to demonstrate a significant difference with placebo.[296,297] Several factors may explain the discrepancies in results of the different clinical trials with naltrexone. Many of the studies included small sample sizes and may lack the statistical power to demonstrate treatment effects.[275] Several large sufficiently powered studies also reported negative results.[296–298]

The combined pharmacotherapies and behavioral interventions for alcohol dependence (COMBINE) trial[223] clearly supports the effectiveness of naltrexone in that each of the groups of patients receiving naltrexone in conjunction with MM had a higher percentage of days abstinent than had those receiving placebo plus MM without naltrexone or combined behavioral intervention (CBI). Naltrexone also reduced the risk of heavy drinking. Extended-release naltrexone injection 380 mg is safe and well tolerated in alcohol-dependent individuals.[299] In two double-blind, randomized, placebo-controlled trials, the efficacy of once-monthly extended-release injectable or depot forms of naltrexone was demonstrated.[229,300,301] which suggests the advantage of increased compliance. Garbutt et al[229] reported that males receiving naltrexone injection had significantly better treatment outcomes than did females, and females who received naltrexone demonstrated no difference from those who received placebo. In addition, because a robust effect was seen for naltrexone injection compared with placebo for people coming into the study abstinent, the FDA required the manufacturer to place a requirement for abstinence when starting the medication on its product information. In the primary care setting, naltrexone injection

given for 3 months and offered with physician-delivered MM was found to be effective in the treatment of alcohol dependence.[302]

Dose

Naltrexone has been approved for use in the first 90 days of abstinence when the risk of relapse is highest. It has also been shown to be safe and well tolerated by patients for periods of up to a year. Treatment with naltrexone should continue based on the response to the medication. Discontinuation should only be considered in consultation with the health care provider. Naltrexone is available as both an oral tablet and a 28-day long-acting injectable.[237,303] Typical adverse effects include nausea, dizziness, sedation, and headache. These adverse effects tend to be mild, and study dropouts because of adverse effects were similar to those with placebo.[304] The usual dose of naltrexone is 50 mg daily, although doses of 25 to 100 mg daily have been reported to be effective, particularly in those with lower blood concentrations of the drug.[302] Side effects, such as nausea or headache, are more common in the initial few days of therapy. Naltrexone should be initiated at least five half-lives after the cessation of any opioid the patient may have been taking, to avoid the induction of opioid withdrawal.[279,303,305] Starting with a 25-mg dose (half a tablet) for the first two to four daily doses may reduce the incidence of side effects.[306,307]

The 380-mg long-acting injectable formulation is given as a gluteal IM injection every 28 days. Patients may prefer this option, particularly in circumstances where daily adherence to oral medications could be difficult to maintain.[308] The 380-mg long-acting injectable formulation has an initial peak that occurs within 2 hours and a second peak that occurs at day 2. This long-acting formulation then plateaus with a resultant steady decrease in blood concentrations starting at day 14. The long-acting formulation has a half-life of 5 days and provides an almost twofold increase in steady-state concentrations of naltrexone over the 50 mg given orally and a

fourfold increase in the metabolite 6-β-naltrexol because of the lack of first-pass metabolism.[308]

Contraindications, Warnings, and Interactions

Naltrexone is contraindicated in patients with a history of sensitivity to naltrexone with acute hepatitis or liver failure and in those who are physically dependent on opioids, receiving opioid analgesics, or in acute opioid withdrawal. The benefit of using naltrexone during pregnancy should clearly outweigh the risk. The concurrent administration of naltrexone and opioid analgesics is contraindicated. To avoid triggering an acute abstinence syndrome, patients must be opioid free for a minimum of 7 to 14 days before initiating treatment with naltrexone, as substantiated with a urine drug test. Although rarely performed, a naloxone challenge test can be used before treatment with naltrexone to rule out concurrent use of opioids. Naltrexone is in the FDA pregnancy category C, and it is unknown whether naltrexone passes into breast milk.

A possible clinical concern with naltrexone tablets or long-acting injectable naltrexone is pain management. Any attempt to overcome the opioid blockade produced by naltrexone using exogenous opioids may result in fatal OD. Should a patient be in pain after receiving an injection, the first drug of choice should be a nonopioid, such as a nonsteroidal anti-inflammatory drug (NSAID). If the patient is still in pain, an opiate can be used, but it will most likely have to be administered in a higher dose and more frequently. When reversal of naltrexone blockade is required for pain management, patients should be monitored in a setting equipped and staffed for cardiopulmonary resuscitation and monitored for signs of respiratory depression.

In a yearlong safety study, the most common side effects were nausea, dizziness, sedation, headache, anxiety, and blurred vision.[309] Should such side effects occur, reducing the dosage by one-half often reduces the side effects. Large doses (eg, 200 mg) of naltrexone can cause liver failure. Patients should report excessive

tiredness, unusual bleeding or bruising, loss of appetite, pain in the upper right part of the stomach, any discoloration of the skin or eyes, a change in stool color or urine, thoughts of suicide, or signs of pneumonia. Patients receiving extended-release naltrexone injection must also monitor the injection site for any type of reaction, for example, swelling, tenderness, bruising, or redness (69% for naltrexone vs 50% for placebo). Reactions that do not resolve in 2 weeks may result in induration, cellulitis, abscess, sterile abscess, or necrosis. Some patients may need to be evaluated for surgical intervention.[309]

COMBINATION PHARMACOTHERAPY

Combination therapy consisting of any of the three FDA-approved drugs in younger adults has been shown to be safe and is possibly more beneficial than is monotherapy.[3,279,303,310] Because disulfiram is potentially unsafe in older adult patients, combination therapy should be limited to acamprosate and naltrexone. The rationale for combining medications is that acamprosate reduces negative reinforcement and naltrexone attenuates positive reinforcement.[171] To test this hypothesis, a randomized, controlled study of 160 patients performed in Europe demonstrated that although combining naltrexone and acamprosate was more effective than was either placebo or acamprosate alone, adding acamprosate was not significantly more effective than was naltrexone alone.[287] In the much larger study, the COMBINE trial randomized >1300 individuals in a double-blind manner to receive placebo, naltrexone, or acamprosate alone or in combination with MM or CBI.[223] Results from this study suggest that acamprosate has no significant effect on drinking versus placebo, either by itself or with any combination of the other treatments in the study. Furthermore, patients receiving placebo and MM from a health care professional had better outcomes than did patients receiving CBI (a CBT-like therapy that includes 12-step facilitation) alone. From the available evidence, it is acceptable to

combine acamprosate with naltrexone with the expectation that in some patients it may not be any more effective than is naltrexone alone.

Topiramate

For patients who did not respond to naltrexone and acamprosate or are intolerant to either agent, topiramate may be offered.[303] Topiramate has multiple mechanisms of action, including enhanced $GABA_A$ inhibition that results in decreased DA facilitation in the midbrain, thought to be of potential benefit in the treatment of AUD, maintenance treatment.[311] In addition, it causes antagonism of kainate to activate the kainate/AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) glutamate receptor subtypes and inhibition of type II and IV carbonic anhydrase isoenzymes.[312] Topiramate is not FDA approved for the treatment of AUD.

A randomized, double-blind, placebo-controlled trial used an escalating dose from 25 to 300 mg/day of topiramate or matching placebo in 150 alcohol-dependent males and females during the first 8 weeks of a 12-week period.[222] Patients stayed at the same dose for the last 4 weeks of the study. All patients in the study received brief behavioral compliance enhancement therapy (BBCET) that was a 10- to 15-minute meeting with a health care professional that focused on resolving side effect issues and facilitated adherence. Participants receiving topiramate reported significantly fewer drinks per day and drinks per drinking day, significantly fewer drinking days, significantly more days of abstinence, and significantly less craving than did those on placebo. The evidence suggests that although abstinence was not a goal at the start of the topiramate study, the medication may be more beneficial during the abstinence initiation phase of treatment.[313] In a phase II clinical trial, the use of topiramate for alcohol dependence treatment was confirmed by outcomes demonstrating that topiramate recipients showed a significantly greater lowering of percentage of heavy drinking days and drinks per drinking day, and a higher percentage of days

abstinent. Topiramate is a non–FDA-approved medication that is beneficial in AUD treatment.[314] In a three-arm study with placebo and naltrexone, topiramate showed statistically significant improvements compared with placebo for time to first relapse (P = .01), cumulative abstinence duration (P = .02), heavy drinking weeks (P = .02), and continuous abstinence at 4 and 8 weeks (P = .01). Topiramate also improved these outcomes compared with naltrexone; however, the results were not statistically significant.[315]

In the treatment of alcohol dependence, topiramate is titrated from 25 mg/day up to 300 mg/day over a 6-week period (100 mg in the morning; 200 mg in the afternoon) or to the patient's maximal tolerable dose. Abrupt discontinuation of topiramate has been associated with seizures in patients without a history of seizures, and, for this reason, gradual withdrawal of the drug (eg, a 25% decrease in the dosage every 4 days for 16 days) is recommended.

In addition to paresthesias (tingling in the extremities), other prominent side effects include mental confusion, slowness in thinking, depression, and somnolence, which may be attenuated by titration when initiating therapy, and the development of renal calculi in about 1.5% of patients.[316] Adequate hydration is encouraged, particularly in patients who may be at risk for developing calculi. Topiramate can cause drowsiness, dizziness, changes in memory, a change in taste (particularly with carbonated beverages), vision changes (particularly associated with increased intraocular pressure), pressure to the touch, loss of appetite or weight loss, and sudden changes in mood.

CONTRAINDICATIONS, WARNINGS, AND INTERACTIONS

Topiramate is contraindicated in those hypersensitive to the drug. Topiramate should be used with caution in those who have a history of urolithiasis, paresthesias, secondary angle-closure glaucoma, renal or hepatic impairment, and conditions or therapies that predispose to acidosis (eg, renal disease, severe respiratory disorders, status epilepticus, diarrhea, surgery, ketogenic diet, or drugs). Monitoring for hyperchloremic non–ionic-gap metabolic

acidosis is essential, and therefore baseline chemistry (eg, HCO_3^- and pH) should be assessed and monitored regularly thereafter. Metabolic acidosis can cause symptoms such as tiredness and loss of appetite, or more serious conditions including arrhythmia or coma. Topiramate has been found to be teratogenic in animal studies, and is a pregnancy category C medication.[316]

Concomitant use of oral contraceptives, phenytoin, carbamazepine, and valproic acid has been found to interact with topiramate.[258] Coadministration of another carbonic anhydrase inhibitor, such as acetazolamide, may increase the possibility of renal stone formation and should be avoided.

Gabapentin

Gabapentin has been studied for the treatment of AWS and maintenance with mixed results. Gabapentin has a regulatory effect on GABA and glutamate brain signaling by binding to the α2δ-1 subunit calcium channel.[317] The American Psychiatric Association's most recent guideline states that patient preferences should be considered when deciding between gabapentin and topiramate.[303] In a double-blind, randomized, placebo-controlled trial of 90 subjects over 16 weeks, gabapentin was more beneficial on the percentage of heavy drinking and abstinent days (P = .04 and P = .02, respectively) than was placebo for those entering the study experiencing high AWS.[318] In subjects showing low AWS at study entry, the gabapentin arm had worse results than had placebo for heavy drinking and abstinent days, although this was not statistically significant. This may suggest a benefit of gabapentin on withdrawal symptoms that could reduce early sobriety relapse. Dizziness was higher in the gabapentin group (57%) than that in placebo (33%). Gabapentin was well tolerated at doses of 600 to 1800 mg given three times daily.[318–320] A concern with gabapentin in the older adult population is its association with increased falls. According to the 2019 Beers Criteria, gabapentin should be used with caution or avoided in older adults because of its strict dependence on renal function for

excretion and the subsequent dizziness that may occur if doses are too high. This risk increases if gabapentin is added to an opioid.[321] Another risk with gabapentin is its abuse potential, with rates of 22% in substance use treatment centers.[322,323]

COMORBIDITIES IN ALCOHOL USE DISORDER

It is quite common for patients who are involved in harmful drinking to have comorbid medical issues. Alcohol has significant drug interactions with many medications (**Table 90-8**). Clinicians must also consider the potential for comorbid psychiatric disorders, (also known as dual diagnosis, eg, depression, bipolar disorder, or schizophrenia) combined with a substance use disorder. Tobacco and caffeine dependence are common.[324] Increased comorbid conditions lead to a poorer treatment prognosis for both medical and psychiatric conditions.

Table 90-8
Ethanol–Drug Interactions

Acetaminophen	Chronic excessive alcohol consumption increases susceptibility to acetaminophen-induced hepatotoxicity. Acute intoxication theoretically protects against acetaminophen toxicity because less hepatotoxic metabolite is generated.
Anticoagulants (oral)	Chronic ethanol consumption induces hepatic metabolism of warfarin, decreasing the hypoprothrombinemic effect. Very large acute ethanol doses (>3 drinks/day) may impair the metabolism of warfarin and increase the hypothrombinemic effect. Vitamin K–dependent clotting factors may be reduced in alcoholics with liver disease, also affecting coagulation.
Antidepressants	Enhanced sedative effects of alcohol and psychomotor impairment are possible. Acute ethanol impairs metabolism. Fluoxetine, paroxetine, fluvoxamine, and probably other SSRIs do not interfere with psychomotor or subjective effects of ethanol.
Ascorbic acid	Ascorbic acid increases ethanol clearance and serum triglyceride levels and improves motor coordination and color discrimination after ethanol consumption.

Barbiturates	Phenobarbital decreases blood ethanol concentration; acute intoxication inhibits pentobarbital metabolism; chronic intoxication enhances hepatic pentobarbital metabolism.
Benzodiazepines	Psychomotor impairment increases with the combination.
Bromocriptine	Ethanol increases gastrointestinal side effects of bromocriptine.
Caffeine	Caffeine has no effect on ethanol-induced psychomotor impairment.
Calcium channel blockers	Verapamil inhibits ethanol metabolism and increases intoxication.
Cephalosporin antibiotics	Ethanol produces flushing, nausea, headaches, tachycardia, and hypotension. Cephalosporin antibiotics that have an ethyl tetrazole thiol side chain produce this disulfiram-like reaction (eg, cefoperazone, cefamandole, and cefotetan).
Chloral hydrate	Elevation of plasma trichloroethanol (a chloral hydrate metabolite) and blood ethanol may occur. Combined CNS depression. Vasodilation, tachycardia, headache
Chloroform	Ethanol increases chloroform hepatotoxicity.
Doxycycline	Chronic consumption of ethanol induces hepatic metabolism of doxycycline and may lower serum concentration of the antibiotic.
Erythromycin	Ethanol may interfere with absorption of the ethylsuccinate salt. Effects on other formulations are unknown.
Furazolidone	When ethanol is ingested, nausea, flushing, light-headedness, and dyspnea may occur (ie, a disulfiram-like reaction).
H_2 antagonists	Cimetidine potentiates ethanol effects. Increases peak plasma ethanol concentrations and area under the plasma ethanol concentration–time curve. CNS toxicity from increased cimetidine serum concentration. Nizatidine and ranitidine may also increase BALs slightly by inhibiting gastric alcohol dehydrogenase. Famotidine does not affect BALs.
Isoniazid	Consumption of ethanol with isoniazid increases the risk of hepatotoxicity. Tyramine-containing alcoholic beverages may cause hypertensive reaction.
Ketoconazole and metronidazole	When ethanol is ingested, nausea, flushing, light-headedness, and dyspnea may occur (ie, a disulfiram-like reaction may occur with metronidazole). A sunburn-like

	rash has been reported with ethanol consumption and ketoconazole. A similar reaction may occur with itraconazole, although no reports exist.
Meprobamate	Synergistic CNS depression may occur.
Metoclopramide	Enhances sedative effects of ethanol
Monoamine oxidase inhibitors	Tyramine-containing alcoholic beverages (eg, wines and beer) may cause a hypertensive crisis. Pargyline may inhibit aldehyde dehydrogenase and cause a disulfiram-like interaction with ethanol.
Narcotic analgesics	Volume of distribution of intravenous meperidine increases with increasing ethanol consumption. Clinical significance unknown; potential for enhanced CNS depression
Oral hypoglycemic agents	Chlorpropamide, tolbutamide, and tolazamide may cause flushing, light-headedness, nausea, and dyspnea if alcohol is ingested (ie, a disulfiram-like reaction).
Paraldehyde	Possible metabolic acidosis may occur.
Phenothiazines	Potentiates psychomotor effects of ethanol
Quinacrine	Possibly inhibits acetaldehyde oxidation
Salicylates	Increases gastric bleeding associated with aspirin; may increase the chance of gastrointestinal hemorrhage
Tetrachloroethylene	Combined CNS depression may occur.
Trichloroethylene	Flushing, lacrimation, blurred vision, and tachypnea may occur when patients exposed to trichloroethylene drink alcohol.

BALs, blood alcohol levels; CNS, central nervous system; SSRIs, serotonin reuptake inhibitors.

Principles for the optimal treatment of patients with a dual diagnosis include the following: (a) flexibility (eg, although the goal of treatment may be abstinence, for some patients, movement in the right direction is just as important to keep the person engaged in treatment); (b) repetition (eg, a constant refocusing of attention for avoiding alcohol and for confronting their psychiatric symptoms is a priority); and (c) counseling (eg, matching patients to the appropriate intervention). These factors are all fundamental to long-lasting

treatment success. Medications, when appropriate (eg, early and vigorous drug intervention with nonaddictive medications), may also help the patient stay in treatment; however, every effort must be made to use medications that do not induce euphoria or cause dependence, and are effective and safe even during relapse.[2,3]

Patients with both drug use and psychiatric disorders constitute a substantial and challenging subpopulation. AUD and major depressive disorder are associated with an odds ratio (OR) of 2.42 (95% confidence interval [CI], 2.22–2.64), and anxiety disorder if associated with an OR of 2.11 (95% CI, 2.03–2.19).[325] Patients with bipolar disorder have comorbid AUD at rates of up to 45%.[326] One reason is the effect of depression, anxiety, and mania on prompting the use of alcohol to mask these symptoms or diminish their intensity.[325,327] This frequent act of self-medicating leads to physical dependence and subsequent cycling of withdrawal. Relapse often occurs to prevent symptoms of alcohol withdrawal and treat unmasked symptoms. The neurotoxicity associated with frequent alcohol use results in mood dysregulation and anxiety, which can cause even more alcohol use to cope with these symptoms. Treating the AUD alone predicts a poorer outcome for other disorders including early relapse. Early and aggressive treatment for each condition should be implemented. Furthermore, care must be taken to ensure that the medications prescribed are safe if combined with alcohol.[3]

Tobacco Use and Dependence

Andrea S. Franks and Sarah E. McBane

CORE PRINCIPLES		CHAPTER CASES
1	Cigarette smoking is the single most preventable cause of premature death in the United States. Smoking harms nearly every organ of the body, causing many diseases (including, but not limited to, cardiovascular disease, pulmonary disease, and cancers) and reducing the health of smokers in general. Quitting smoking has immediate- and long-term benefits, reducing risks for diseases caused by smoking and improving health in general.	**Case 91-2 (Questions 1, 4) Case 91-3 (Question 1) Case 91-5 (Question 1) Case 91-6 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
2	Tobacco products are effective delivery systems for the drug nicotine. Nicotine is a highly addictive drug that activates the dopamine reward pathway in the brain that reinforces continued tobacco use. Nicotine withdrawal symptoms (eg, irritability, anxiety, difficulty concentrating, restlessness, depressed mood, insomnia, impaired performance, increased appetite or weight gain, and cravings) generally occur when nicotine is discontinued.	**Case 91-1 (Questions 2, 4) Case 91-3 (Question 1) Case 91-6 (Questions 1, 2)**
3	Constituents in tobacco smoke are associated with a number of clinically significant drug interactions.	**Case 91-4 (Questions 1, 3) Case 91-6 (Question 3)**
4	Tobacco dependence, a chronic disease that often requires repeated intervention and multiple attempts to quit, is characterized by physiologic dependence (addiction to nicotine) and behavioral habit of using tobacco.	**Case 91-1 (Question 5) Case 91-2 (Question 3) Case 91-3 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
5	Numerous effective medications, as delineated in the Clinical Practice Guideline, are available for treating tobacco use and dependence. Most patients should be encouraged to use one or more first-line agents, which include the nicotine patch, nicotine gum, nicotine lozenge, nicotine nasal spray, nicotine oral inhaler, sustained-release bupropion, and varenicline. All first-line agents approximately double quit rates; therefore, the choice of therapy is based largely on contraindications, precautions, patient preference, and tolerability. In some cases, medications can be combined or used for extended durations.	**Case 91-1 (Questions 1–3) Case 91-2 (Questions 3, 4) Case 91-3 (Question 1) Case 91-4 (Question 2) Case 91-6 (Questions 1, 4)**

CORE PRINCIPLES		CHAPTER CASES
6	Comprehensive counseling, as defined by the Clinical Practice Guideline, includes asking about tobacco use, advising patients to quit, assessing readiness to quit, assisting patients with quitting, and arranging follow-up. This patient-centered approach is referred to as the "*5 A's*." Counseling and support can be provided in a variety of ways, such as through individual counseling, group programs, telephone, or the Internet. Two components of counseling are especially effective and should be applied when assisting patients with quitting: practical counseling (problem-solving or skills training) and social support delivered as part of treatment. Relapse is common, and clinicians should work with patients throughout the quit attempt to increase the chances for long-term abstinence.	**Case 91-1 (Questions 2, 5) Case 91-3 (Question 1) Case 91-5 (Question 1) Case 91-6 (Questions 1, 2, 4)**
7	Brief tobacco dependence treatment (>3 minutes) is effective. In the absence of time or expertise, ask about tobacco use, advise patients to quit, and refer patients to other resources (eg, telephone quitlines, web-based support, and local programs) for additional assistance. This approach is referred to as "Ask-Advise-Refer."	**Case 91-5 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
8	Patients with psychiatric disorders exhibit a higher prevalence of tobacco use and a disproportionately high level of tobacco-related morbidity and mortality.	**Case 91-6 (Question 1)**
9	Cigarettes are the most common form of tobacco used in the United States; however, other forms of tobacco exist (spit tobacco, pipes, cigars, bidis, and hookah). All forms of tobacco are harmful.	**Case 91-2 (Question 2)**

INTRODUCTION

Tobacco is a detrimental substance, and its use dramatically increases a person's odds of dependence, disease, disability, and death. Tobacco products are carefully engineered formulations that optimize the delivery of nicotine, a chemical that meets the criteria for an addictive substance: (a) nicotine induces psychoactive effects, (b) it is used in a highly controlled or compulsive manner, and (c) behavioral patterns of tobacco use are reinforced by the pharmacologic effects of nicotine.[1] As a major risk factor for a wide range of diseases, including cardiovascular conditions, cancers, and pulmonary disorders, tobacco is the primary known preventable cause of premature death and disease in our society.[2]

In the United States, smoking is responsible for >480,000 premature deaths each year.[2] In addition to the harm imposed on users of tobacco, exposure to secondhand smoke results in an estimated 50,000 deaths annually.[3] According to the Office of the U.S. Surgeon General, there is no risk-free level of exposure to

tobacco smoke.[1] Because of the health and societal burdens that it imposes, tobacco use and dependence should be addressed during each clinical encounter with all tobacco users.[4]

EPIDEMIOLOGY OF TOBACCO USE AND DEPENDENCE

In the United States, cigarettes are the most commonly consumed form of tobacco, but other forms are also prevalent: smokeless tobacco (chewing tobacco and oral snuff), pipes, cigars, clove cigarettes, bidis, and hookah. Electronic cigarettes (or e-cigarettes), which are growing in popularity, are electronic nicotine delivery systems (ENDSs) containing liquid nicotine and other substances that are heated by an atomizer and inhaled as a vapor. Among adults, smoking prevalence varies by sociodemographic factors, including sex, race or ethnicity, education level, age, and poverty level. In 2019, ~21% of adults in the United States used a tobacco product, with 14% reporting cigarette use.[5]

Factors Contributing to Tobacco Use

Tobacco addiction is maintained by nicotine dependence.[6,7] Nicotine induces a variety of pharmacologic effects that lead to dependence.[8] However, tobacco dependence is not simply a matter of nicotine pharmacology—it is a result of the interplay of complex processes, including the desire for the direct pharmacologic actions of nicotine, the relief of withdrawal, learned associations, and environmental cues (eg, advertising, the smell of a cigarette, or observing others who are smoking).[7] Physiologic factors, such as preexisting medical conditions (eg, psychiatric comorbidities[7,9] and genetic profile), also can predispose individuals to tobacco use.[8,10]

Nicotine, the addictive component of tobacco, is rapidly absorbed and passes through the blood–brain barrier, contributing to its

addictive nature. After inhalation, the nicotine reaches the brain within seconds.[6] As such, smokers experience nearly immediate onset of the positive effects of nicotine, including pleasure, relief of anxiety, improved task performance, improved memory, mood modulation, and skeletal muscle relaxation.[6] These effects, mediated by alterations in neurotransmitter levels, reinforce continued use of nicotine-containing products.[6,7]

Nicotine Pharmacology

Nicotine (*Nicotiana tabacum*) is a clear, weak base with a pK_a of 8.0.[11] In acidic media, nicotine is ionized and poorly absorbed; conversely, in alkaline media, nicotine is nonionized and well absorbed. Under physiologic conditions (pH = 7.4), a large proportion of nicotine is nonionized and readily crosses cell membranes.[11] The tobacco industry and pharmaceutical companies are able to adjust the pH of their tobacco products and nicotine replacement therapy (NRT) products to maximize the absorption potential of nicotine.[11–13]

Once absorbed, nicotine induces a variety of central nervous system, cardiovascular, and metabolic effects. Nicotine stimulates the release of several neurotransmitters, inducing a range of pharmacologic effects such as pleasure (dopamine), arousal (acetylcholine and norepinephrine), cognitive enhancement (acetylcholine), appetite suppression (dopamine, norepinephrine, and serotonin), learning (glutamate), memory enhancement (glutamate), mood modulation (serotonin), and reduction of anxiety and tension (β-endorphin and γ-aminobutyric acid [GABA]).[14] The dopamine reward pathway, a network that elicits feelings of pleasure in response to certain stimuli, is central to the drug-induced reward. Immediately after inhalation, a bolus of nicotine enters the brain, stimulating the release of dopamine, which induces nearly immediate feelings of pleasure, along with relief of the symptoms of nicotine withdrawal. This rapid dose response reinforces repeated administration of the drug and perpetuates the smoking behavior.[7,14]

Chronic administration of nicotine has been shown to increase the number of nicotine receptors in specific regions of the brain.[15] The increase in receptors could play a role in nicotine tolerance and dependence.[14,15] Chronic nicotine administration also leads to tolerance of its behavioral and cardiovascular effects during the course of the day; however, tobacco users regain sensitivity to the effects of nicotine after overnight abstinence from nicotine,[6,7] as shown in **Figure 91-1**.[16] After smoking the first cigarette of the day, the smoker experiences marked pharmacologic effects, particularly arousal. No other cigarette throughout the day produces the same degree of pleasure or arousal. For this reason, many smokers describe the first cigarette as the most important one of the day. Shortly after the initial cigarette, tolerance begins to develop. Accordingly, the threshold levels for both pleasure or arousal and abstinence rise progressively throughout the day because the smoker becomes tolerant to the effects of nicotine. With continued smoking, nicotine accumulates, leading to an even greater degree of tolerance. Each cigarette after the first one produces less pleasure and arousal, and primarily serves to alleviate withdrawal symptoms. Lack of exposure to nicotine overnight results in resensitization of drug responses (ie, loss of tolerance). Tobacco users become adept at titrating their nicotine levels by smoking a certain number of cigarettes per day or consuming sufficient nicotine per day to achieve the desired effects of cigarette smoking and minimize the symptoms of nicotine withdrawal.[7,16] Withdrawal symptoms, which include anger, anxiety, depression, difficulty concentrating, impatience, insomnia, and restlessness, typically manifest within a few days of quitting, peak within a week, and subside within 2 to 4 weeks.[17]

Nicotine is extensively metabolized in the liver and, to a lesser extent, in the kidney and lung. Approximately 70% to 80% of nicotine is metabolized to cotinine, an inactive metabolite.[11] The rapid metabolism of nicotine (half-life [$t_{1/2}$] = 2 hours) to inactive compounds underlies tobacco users' needs for frequent, repeated administration. The half-life of cotinine, however, is much longer ($t_{1/2}$ = 18–20 hours), and, for this reason, cotinine is commonly used as a marker of tobacco use as well as a marker for exposure to secondhand smoke.[11] Measurement of cotinine cannot, however, differentiate between the nicotine from tobacco products and the nicotine from NRT products. Nicotine and other metabolites are excreted in the urine. Urinary excretion is pH dependent; the

excretion rate is increased in acidic urine.[11] Nicotine crosses the placenta and accumulates in breast milk.[11]

Drug Interactions With Smoking

It is widely recognized that polycyclic aromatic hydrocarbons (PAHs) in tobacco smoke are responsible for most drug interactions with smoking.[18,19] PAHs, which result from incomplete combustion of tobacco, are potent inducers of several hepatic cytochrome-P450 (CYP) microsomal enzymes (CYP1A1, CYP1A2, and, possibly, CYP2E1). Although other substances in tobacco smoke, including acetone, pyridines, benzene, nicotine, carbon monoxide, and heavy metals (eg, cadmium), might also interact with hepatic enzymes, their effects appear to be less significant. Most drug interactions with tobacco smoke are pharmacokinetic, resulting from the induction of drug-metabolizing enzymes (especially CYP1A2) by compounds in tobacco smoke. **Table 91-1** summarizes key interactions with smoking.[18–20] Patients who begin smoking, quit smoking, or dramatically alter their level of smoking might require dosage adjustments for some medications.

Table 91-1
Clinically Significant Drug Interactions With Tobacco Smoke

Drug/Class	Mechanism of Interaction and Effects
Bendamustine (Treanda®)	Metabolized by CYP1A2. Manufacturer recommends using with caution in smokers because of likely ↓ bendamustine concentrations, with ↑ concentrations of its two active metabolites.
Caffeine	↑ Metabolism (induction of CYP1A2); ↑ clearance (56%) Caffeine levels likely increase after cessation.
Clopidogrel (Plavix®)	↑ Metabolism (induction of CYP1A2) of clopidogrel to its active metabolite Clopidogrel's effects are enhanced in smokers (≥10 cigarettes/day): significant ↑ platelet inhibition, ↓ platelet aggregation; although improved clinical outcomes have been shown, may also ↑ risk of bleeding.

Drug/Class	Mechanism of Interaction and Effects
Clozapine (Clozaril®)	↑ Metabolism (induction of CYP1A2); ↓ plasma concentrations (18%) ↑ Levels on cessation may occur; closely monitor drug levels and reduce the dose as required to avoid toxicity.
Erlotinib (Tarceva®)	↑ Clearance (24%); ↓ trough serum concentrations (twofold)
Fluvoxamine (Luvox®)	↑ Metabolism (induction of CYP1A2); ↑ clearance (24%); ↓ AUC (31%); ↓ C_{max} (32%) and C_{ss} (by 39%) Dosage modifications not routinely recommended, but smokers may need ↑ dosages.
Irinotecan (Camptosar®)	↑ Clearance (18%); ↓ serum concentrations of active metabolite SN-38 (~40%; via induction of glucuronidation); ↓ systemic exposure resulting in lower hematologic toxicity and may reduce efficacy. Smokers may need ↑ dosages.
Olanzapine Zyprexa®)	↑ Metabolism (induction of CYP1A2): ↑ clearance (98%); ↓ serum concentrations (12%) Dosage modifications not routinely recommended, but smokers may need ↑ dosages.
Riociguat (Adempas®)	↓ Plasma concentrations (by 50%–60%) Smokers may require dosages higher than 2.5 mg 3 times daily; consider dose reduction upon cessation.
Ropinirole (Requip®)	↓ C_{max} (30%) and AUC (38%) in a study with patients with restless legs syndrome Smokers may need ↑ dosages.
Tacrine (Cognex®)	↑ Metabolism (induction of CYP1A2); ↓ half-life (50%); serum concentrations threefold lower. Smokers may need ↑ dosages.
Theophylline (Theo-Dur®, etc)	↑ Metabolism (induction of CYP1A2); ↑ clearance (58%–100%); ↓ half-life (63%) Levels should be monitored if smoking is initiated, discontinued, or changed. ↑ Clearance with secondhand smoke exposure Maintenance doses are considerably higher in smokers; ↑ clearance also with secondhand smoke exposure.

Drug/Class	Mechanism of Interaction and Effects
Hormonal contraceptives (combined)	↑ Risk of cardiovascular adverse effects (eg, stroke, myocardial infarction, or thromboembolism) in females who smoke and use combined hormonal contraceptives ↑ Risk with age and with heavy smoking (≥15 cigarettes/day) and is quite marked in females age 35 and older

AUC, area under the curve; C_{max}, maximal concentration; C_{ss}, steady-state concentration; CYP, cytochrome P450; INR, international normalized ratio; PD, pharmacodynamics; PK, pharmacokinetics.

Health Consequences of Tobacco Use

All forms of tobacco are harmful, and there is no safe level of exposure to tobacco products. Smoking has a causal or contributory role in the development of a variety of medical conditions, affecting almost every organ in the body.[1,2]

Benefits of Quitting

Benefits of smoking cessation incurred soon after quitting (eg, within 2 weeks–3 months) include improvements in pulmonary function, circulation, and ambulation. Smoking cessation results in measurable improvements in lung function (see Chapter 19, Chronic Obstructive Pulmonary Disease). One year after cessation, the excess risk of coronary heart disease (CHD) is reduced to half that of continuing smokers. After 5 to 15 years, the risk of stroke is reduced to a rate similar to that of people who are lifetime nonsmokers; and 10 years after quitting, the chance of dying of lung cancer is approximately half that of continuing smokers. In addition, the risk of developing mouth, throat, esophagus, bladder, kidney, or pancreatic cancer is decreased. Finally, 15 years after quitting, the risk of CHD is reduced to a rate that is similar to that of people who have never smoked.[21] Similarly, more recent data suggest that smokers who quit for good over a sustained period have an overall

mortality rate and death rate associated with cardiovascular disease, ischemic heart disease, and stroke that is similar to individuals who have never smoked. In contrast, individuals who had successfully quit, but later resumed smoking, had mortality risks that were significantly higher than that of lifetime nonsmokers.[22]

On average, cigarette smokers die ~10 years younger than do nonsmokers, and of those who continue smoking, at least half will eventually die from a tobacco-related disease. A reduction in smoking does not equate to a reduction in harm,[,23] and even low levels of smoking (eg, one to four cigarettes per day) have documented risks.[24,25] Therefore, decreasing the number of cigarettes smoked per day is a positive step toward quitting, but should not be recommended as a targeted end point. For any patient who uses tobacco, the goal is complete, long-term abstinence from all nicotine-containing products.

Tobacco Use and Dependence: Treatment Approaches

Most tobacco users attempt to quit without assistance, even though those who receive assistance are more likely to be successful in quitting.[4,26] Given the complexity of the tobacco dependence syndrome and the constellation of factors that contribute to tobacco use, treatment requires a multifaceted approach. The U.S. Public Health Service Clinical Practice Guideline for Treating Tobacco Use and Dependence notes that clinicians can have an important impact on their patients' ability to quit.[4] A meta-analysis of 29 studies estimated that compared with patients who do not receive an intervention from a clinician, patients who receive a tobacco-cessation intervention from a physician clinician or a nonphysician clinician are 2.2 and 1.7 times, respectively, more likely to quit (at 5 or more months after cessation).[4] Other effective methods for delivery of counseling include group programs[4,27] and telephone counseling.[28] Internet- and text message–based interventions have also shown small positive effects on cessation.[29,30]

Numerous effective medications are available for tobacco dependence, and clinicians should encourage their use by all patients attempting to quit smoking—except when medically contraindicated or with specific populations for which there is insufficient evidence of effectiveness (eg, pregnant females, smokeless tobacco users, light smokers, and adolescents). [4] Although both pharmacotherapy and behavioral counseling are effective independently, patients' odds of quitting are substantially increased when the two approaches are used simultaneously.[31] Clinicians can have a significant impact on a patient's likelihood of success by recommending pharmacotherapy agents and by supplementing medication use with behavioral counseling, as described later in this chapter.

Assisting Patients With Quitting

BEHAVIORAL COUNSELING STRATEGIES

According to the Clinical Practice Guideline,[4] five key components constitute comprehensive, patient-centered counseling for tobacco cessation: (1) asking patients whether they use tobacco, (2) advising tobacco users to quit, (3) assessing patients' readiness to quit, (4) assisting patients with quitting, and (5) arranging follow-up care. These steps are referred to as the "5 A's," and are described, in brief, as follows. Figure 91-1 can be used as a guide for structuring counseling interactions.

1. **Ask**: Clinical care should routinely include screening for tobacco use and should include assessment and documentation of tobacco use status (current, former, or never user) and level of use (eg, number of cigarettes smoked per day) Also, patients should be asked about exposure to secondhand smoke.
2. **Advise**: Tobacco users should be advised to consider quitting; the advice should be clear and compelling, yet sensitively delivered in a tone of voice that communicates concern and a willingness to assist with quitting. When possible, messages should be

personalized by relating advice to factors such as a patient's health status, medication regimen, personal reasons for wanting to quit, or the impact of tobacco use on others.

3. **Assess**: The assessment of a patient's readiness to quit is key to providing appropriate counseling interventions. Patients should be categorized as being (a) not ready to quit in the next month; (b) ready to quit in the next month; (c) a recent quitter, having quit in the past 6 months; or (d) a former user, having quit more than 6 months ago.[4] This classification defines the clinician's next step, which is to provide counseling that is tailored to the patient's level of readiness to quit. The counseling interventions for patients who are ready to quit will be different from those for patients who are not considering quitting.
4. **Assist**: When counseling tobacco users, it is important that clinicians and patients view quitting as a process that might take months or even years to achieve. The goal is to promote forward progress in the process of change, with the target end point being sustained abstinence from all nicotine-containing products.

When counseling patients who are not ready to quit, an important first step is to foster motivation. Some patients are not convinced that quitting is important, but most recognize the need to quit and are simply not ready to make the commitment to do so. Often, patients have tried to quit multiple times and failed, and thus are too discouraged to try again. The "5 R's" can be applied to enhance motivation to quit[4] (**Table 91-2**) by clinicians offering to work closely with the patient in designing a treatment plan. Although it might be useful to educate patients about the pharmacotherapy options, it is inappropriate to prescribe a treatment regimen for patients who are not ready to quit. For patients who are not ready to quit in the next 30 days, encourage them to seriously consider quitting and ask the following questions:

Table 91-2
Enhancing Motivation to Quit: The "5 R's" for Tobacco-

Cessation Counseling

Relevance—Encourage patients to think about the reasons why quitting is important. Counseling should be framed such that it relates to the patient's risk for disease or exacerbation of disease, family or social situations (eg, having children with asthma), health concerns, age, or other patient factors, such as prior experience with quitting.

Risks—Ask patients to identify potential negative health consequences of smoking, such as acute risks (shortness of breath, asthma exacerbations, harm to pregnancy, infertility), long-term risks (cancer, cardiac, and pulmonary disease), and environmental risks (promoting smoking among children by being a negative role model; effects of secondhand smoke on others, including children and pets).

Rewards—Ask patients to identify potential benefits that they anticipate from quitting, such as improved health, enhanced physical performance, enhanced taste and smell, reduced expenditures for tobacco, less time wasted or work missed, reduced health risks to others (fetus, children, housemates), and reduced aging of the skin.

Roadblocks—Help patients identify barriers to quitting and assist in developing coping strategies (Table 91-4) for addressing each barrier. Common barriers include nicotine withdrawal symptoms, fear of failure, a need for social support while quitting, depression, weight gain, and a sense of deprivation or loss.

Repetition—Continue to work with patients who are successful in their quit attempt. Discuss circumstances in which smoking occurred to identify the trigger(s) for relapse; this is part of the learning process and will be useful information for the next quit attempt. Repeat interventions when possible.

Source: Reprinted from Fiore MC, Jaén CR, Baker TB, et al. *Treating Tobacco Use and Dependence: 2008 Update. Clinical Practice Guideline*. U.S. Department of Health and Human Services. Public Health Service; 2008.

1. *Do you ever plan to quit?*

   If the patient responds "no," the clinician should ask, "*What would have to change for you to decide to quit?"* If the patient responds "nothing," then offer to assist, if or when the patient changes his or her mind. If the patient responds "yes," the clinician should continue with question 2.

2. *What might be some benefits of quitting now, instead of later?*

   Quitting often becomes more difficult the longer a patient smokes. Most patients will agree that there is never an ideal time to quit, and procrastinating on a quit date has more negative rather than positive effects.

3. *What would have to change for you to decide to quit sooner?*

This question probes patients' perceptions of quitting, which reveals some of the barriers to quitting that can then be discussed.

For patients who are ready to quit (eg, in the next month), the goal is to work with the patient in designing an individualized treatment plan, addressing the key issues listed under the "Assist" component of Figure 91-1.[20] Clinicians should elicit patients' opinions about the different cessation medications and should work with patients in selecting the quitting methods (eg, medications and behavioral counseling programs). Although it is important to recognize that pharmacotherapy might not be appropriate, desirable, or affordable for all patients, clinicians should educate patients that medications, when taken correctly, can substantially increase the likelihood of success.

Patients should select a quit date, ideally within the next 2 weeks. This allows sufficient time to prepare for the quit attempt, including mental preparation; preparation of the environment; removing all tobacco products and ashtrays from the home, car, and workspace; and soliciting the support of their family, friends, and coworkers. Additional strategies for coping with quitting are shown in **Table 91-3**. Patients should be counseled about withdrawal symptoms, medication use, and the importance of receiving behavioral counseling throughout the quit attempt. Finally, patients should be commended for taking important steps toward improving their health.

Table 91-3

Cognitive and Behavioral Strategies for Tobacco Cessation

Cognitive Strategies
Focus on *retraining the way a patient thinks.* Often, patients will deliberate on the fact that they are thinking about a cigarette, and this leads to relapse. Patients must recognize that thinking about a cigarette does not mean they need to have one.

Cognitive Strategies	
Review commitment to quit	Each morning, say, “I am proud that I made it through another day without tobacco!” Remind oneself that cravings and temptations are temporary and will pass. Announce, either silently or aloud, “I am a nonsmoker, and the temptation will pass.”
Distractive thinking	Deliberate, immediate refocusing of thinking toward other thoughts when cued by thoughts about tobacco use.
Positive self-talks, “pep talks”	Say “I can do this.” Remind oneself of previous difficult situations in which tobacco use was avoided.
Relaxation through imagery	Center mind toward positive, relaxing thoughts.
Mental rehearsal, visualization	Preparing for situations that might arise by envisioning how best to handle them. For example, envision what would happen if offered a cigarette by a friend—mentally craft and rehearse a response, and perhaps even practice it by saying it aloud.
Behavioral Strategies	
Involve *specific actions to reduce risk for relapse*. These strategies should be considered before quitting, after determining patient-specific triggers and routines or situations associated with tobacco use. Given here are strategies for several of the common cues or causes for relapse.	
Stress	Anticipate upcoming challenges at work, at school, or in personal life. Develop a substitute plan for tobacco use during times of stress (eg, use deep breathing, take a break or leave the situation, call a supportive friend or family member, or use nicotine replacement therapy to manage situational cravings).
Alcohol	Drinking alcohol can lead to relapse. Consider limiting or abstaining from alcohol during the early stages of quitting.
Other tobacco users	Quitting is more difficult when around other tobacco users. This is especially difficult if there is another tobacco user in the household. During the early stages of quitting, limit prolonged contact with individuals who are using tobacco. Ask coworkers, friends, and housemates not to smoke or use tobacco in your presence.

Cognitive Strategies	
Oral gratification needs	Have nontobacco oral substitutes (eg, gum, sugarless candy, straws, toothpicks, lip balm, toothbrush, nicotine replacement therapy, or bottled water) readily available.
Automatic smoking routines	Anticipate routines that are associated with tobacco use and develop an alternative plan.
	Examples:
	Morning coffee: Change morning routine, drink tea instead of coffee, take shower before drinking coffee, take a brisk walk shortly after awakening.
	While driving: Remove all tobacco from car, have car interior detailed, listen to an audio book or talk radio, use oral substitutes.
	While on the phone: Stand while talking, limit call duration, change phone location, keep hands occupied by doodling or sketching.
	After meals: Get up and immediately do dishes or take a brisk walk after eating, call supportive friend.
Postcessation weight gain	Do not attempt to modify multiple behaviors at one time. If weight gain is a barrier to quitting, engage in regular physical activity and adhere to a healthful diet (as opposed to strict dieting). Carefully plan and prepare meals, increase fruit and water intake to create a feeling of fullness, and chew sugarless gum or eat sugarless candies. Consider use of pharmacotherapy shown to delay weight gain (eg, nicotine gum, lozenge, or sustained-release bupropion).
Cravings for tobacco	Cravings for tobacco are temporary and usually pass within 5–10 minutes. Handle cravings through distractive thinking, take a break, do something else, take deep breaths.

- **Arrange:** Because patients' success at quitting increases when multiple counseling interactions are provided, it is important to arrange follow-up counseling. Follow-up contact should occur soon after the quit date, preferably during the first week. A second

follow-up contact is recommended within the first month of quitting.[4] Additional follow-up contacts should occur to monitor patient progress, assess compliance with pharmacotherapy regimens, and provide additional support.

Relapse prevention counseling should be part of every follow- up contact with patients who have recently quit smoking. When counseling recent quitters, it is important to address challenges in countering withdrawal symptoms and cravings or temptations to use tobacco. A list of strategies for key triggers or temptations for tobacco use is provided in Table 91-3.[20] Importantly, because tobacco use is a habitual behavior, patients should be advised to alter their daily routines; this helps disassociate specific behaviors from the use of tobacco. Patients who slip and smoke a cigarette (or use any form of tobacco) or experience a full relapse to habitual tobacco use should be encouraged to evaluate the scenario in which tobacco use first occurred and identify the trigger(s) for relapse. This process provides valuable information for future quit attempts.

PHARMACOTHERAPY OPTIONS

All smokers who are trying to quit should be encouraged to use one or more of the U.S. Food and Drug Administration (FDA)-approved pharmacologic aids for cessation. Potential exceptions that require special consideration include use in specific populations that lacks sufficient evidence of effectiveness (eg, pregnant females, smokeless tobacco users, light smokers, and adolescents).[4] Pharmacotherapy should always be combined with behavioral support and counseling. Currently, the FDA-approved first-line agents that have been shown to be effective in promoting smoking cessation include five NRT dosage forms, sustained- release bupropion, and varenicline.[4] The choice of therapy is dictated by considerations such as patient preference for a given agent, previous experience with cessation medications, current medical conditions, previous levels of smoking, medication adherence issues, and the patient’s out-of-pocket costs. Dosing information,

precautions, and adverse effects for the first-line agents are shown in **Table 91-4**.

Table 91-4
Pharmacologic Product Guide: U.S. Food and Drug Administration–Approved Medications for Smoking Cessation

NRT Formulations					Bupropion SR	Varenicline
Gum	**Lozenge**	**Transdermal Patch**	**Nasal Spray**	**Oral Inhaler**		
Product						
Nicorette®,[a] generic	Nicorette Lozenge®[a]; Nicorette Mini Lozenge® (standard and mini),[a] generic	NicoDerm CQ®,[a] Habitrol®,[b] generic	Nicotrol® NS[c]	Nicotrol® inhaler[c]	Generic (formerly Zyban)	Chantix®[c]
OTC	OTC	OTC (NicoDerm CQ®, generic)	Rx	Rx	Rx	Rx
2 and 4 mg	2 and 4 mg	Rx (generic)	Metered spray	10-mg cartridge	150-mg sustained-release tablet	0.5- and 1-mg tablet
Original, cinnamon, fruit, mint	Cherry, mint	7, 14, and 21 mg (24-hour release)	10 mg/mL aqueous solution	Delivers 4 mg of inhaled nicotine vapor		
Precautions, Warnings, and Contraindications						
Temporomandibular joint disease			Underlying chronic nasal disorders (rhinitis, nasal polyps, sinusitis) Severe reactive airway disease	Bronchospastic disease	Concomitant therapy with medications or medical conditions known to lower seizure threshold Hepatic impairment Pregnancy[d] (category C) and breast-feeding Adolescents (>18 years) Treatment-emergent neuropsychiatric symptoms[e]	Severe renal impairment (dosage adjustment is necessary.) Pregnancy[d] (category C) and breast-feeding Adolescents (>18 years) Treatment-emergent neuropsychiatric symptoms[e]
Dosing[f]						
First cigarette ≤30 minutes after waking: 4 mg *First cigarette >30 minutes after waking:* 2 mg Weeks 1–6: 1 piece every 1–2 hours Weeks 7–9: 1 piece every 2–4 hours Weeks 10–12: 1 piece every 4–8 hours Maximum, 24 pieces/day Chew each piece slowly. Park between cheek and gum when peppery or tingling sensation appears (~15–30 chews). Resume chewing when tingle fades.	*First cigarette ≤30 minutes after waking:* 4 mg *First cigarette >30 minutes after waking:* 2 mg Weeks 1–6: 1 lozenge every 1–2 hours Weeks 7–9: 1 lozenge every 2–4 hours Weeks 10–12: 1 lozenge every 4–8 hours Maximum, 20 lozenges/day	*>10 cigarettes/day:* 21 mg/day × 4 weeks (generic) × 6 weeks (NicoDerm CQ®) 14 mg/day × 2 weeks 7 mg/day × 2 weeks *≤10 cigarettes/day:* 14 mg/day × 6 weeks 7 mg/day × 2 weeks Rotate patch application site daily; do not apply a new patch to the same skin site for at least 1 week. May wear patch for 16 hours if patient experiences sleep disturbances (remove at bedtime)	1–2 doses/hour (8–40 doses/day) One dose = 2 sprays (one in *each* nostril); each spray delivers 0.5 mg of nicotine to the nasal mucosa. Maximum –5 doses/hour or –40 doses/day For best results, initially use at least 8 doses/day. Do not sniff, swallow, or inhale through the nose as the spray is being administered.	6–16 cartridges/day Individualize dosing; initially use 1 cartridge every 1–2 hours. Best effects with continuous puffing for 20 minutes Initially use at least 6 cartridges/day. Nicotine in cartridge is depleted after 20 minutes of active puffing. Inhale into back of throat or puff in short breaths.	150 mg PO every morning × 3 days, then increase to 150 mg PO bid Do not exceed 300 mg/day. Begin therapy 1–2 weeks *before* quit date. Allow at least 8 hours between doses. Avoid bedtime dosing to minimize insomnia. Dose tapering is not necessary. Duration: 7–12 weeks, with maintenance up to 6 months in selected patients	Days 1–3: 0.5 mg PO every morning Days 4–7: 0.5 mg PO bid Weeks 2–12: 1 mg PO bid Begin therapy 1 week *before* quit date. Take dose after eating and with a full glass of water. Dose tapering is not necessary. Dosing adjustment is recommended for patients with severe renal impairment.

Repeat chew and park steps until most of the nicotine is gone (tingle does not return; generally 30 minutes). Park in different areas of the mouth. No food or beverages 15 minutes before or during use Duration: up to 12 weeks	Allow to dissolve slowly (20–30 minutes for standard; 10 minutes for mini). Nicotine release may cause a warm, tingling sensation. Do not chew or swallow. Occasionally rotate to different areas of the mouth. No food or beverages 15 minutes before or during use Duration: up to 12 weeks	Duration: 8–10 weeks	Duration: 3–6 months	Do *not* inhale into the lungs (like a cigarette), but "puff" as if lighting a pipe. Open cartridge retains potency for 24 hours. No food or beverages 15 minutes before or during use Duration: 3–6 months		Duration: 12 weeks; an additional 12-week course may be used in selected patients. May initiate up to 35 days before target quit date *or* may reduce smoking over a 12-week period of treatment before quitting and continue treatment for an additional 12 weeks
Adverse Effects						
Mouth or jaw soreness Hiccups Dyspepsia Hypersalivation Effects associated with incorrect chewing technique: Lightheadedness Nausea or vomiting Throat and mouth irritation	Nausea Hiccups Mouth irritation Heartburn Headache Sore throat Dizziness	Local skin reactions (erythema, pruritus, burning) Headache Sleep disturbances (insomnia, abnormal or vivid dreams); associated with nocturnal nicotine absorption	Nasal or throat irritation (hot, peppery, or burning sensation) Rhinitis Tearing Sneezing Cough Headache	Mouth or throat irritation Cough Headache Rhinitis Dyspepsia Hiccups	Insomnia Dry mouth Nervousness or difficulty concentrating Rash Constipation Seizures (risk is ~0.1%) Neuropsychiatric symptoms (rare; see Precautions)	Nausea Sleep disturbances (insomnia, abnormal or vivid dreams) Constipation Flatulence Vomiting Neuropsychiatric symptoms (rare; see Precautions)

NRT, nicotine replacement therapy; OTC, over the counter (nonprescription); Rx, prescription; SR, sustained release.

[a]Marketed by GlaxoSmithKline.

[b]Marketed by Dr. Reddy's.

[c]Marketed by Pfizer.

[d]The U.S. Clinical Practice Guideline states that pregnant smokers should be encouraged to quit without medication based on insufficient evidence of effectiveness and theoretic concerns with safety. Pregnant smokers should be offered behavioral counseling interventions that exceed minimal advice to quit.

[e]In July 2009, the U.S. Food and Drug Administration (FDA) mandated that the prescribing information for all bupropion- and varenicline-containing products includes a black box warning highlighting the risk of serious neuropsychiatric symptoms, including changes in behavior, hostility, agitation, depressed mood, suicidal thoughts and behavior, and attempted suicide. Clinicians should advise patients to stop taking varenicline or bupropion SR and contact a health care provider immediately if they experience agitation, depressed mood, and any changes in behavior that are not typical of nicotine withdrawal, or if they experience suicidal thoughts or behavior. If treatment is stopped because of neuropsychiatric symptoms, patients should be monitored until the symptoms resolve. Based on the results of a mandated clinical trial, the FDA removed this boxed warning in December 2016.

FIRST-LINE AGENTS

Nicotine replacement therapy

NRT improves cessation rates by reducing the physical withdrawal symptoms associated with tobacco cessation, allowing the patient to focus on behavior modification and cope with the psychological aspects of quitting. In addition, because the onset of action for NRT is not as rapid as that of nicotine obtained through smoking, patients become less accustomed to the nearly immediate, reinforcing effects of inhaled nicotine. A meta-analysis found that patients using NRT are 1.6 times as likely to quit smoking than are those receiving placebo.[31] **Figure 91-2** depicts the concentration–time curves for the various NRT formulations, compared with a cigarette and snuff, a smokeless form of tobacco.[32,33] Nicotine nasal spray reaches its peak concentration most rapidly. The nicotine gum, lozenge, and oral inhaler have similar concentration curves, and the nicotine transdermal patch has the slowest onset but offers more consistent blood levels of nicotine for a sustained period. Although ideally tobacco use stops when NRT is initiated, some patients may continue to occasionally use tobacco products after beginning NRT. This allows patients more flexibility with continuing to use NRT if they slip and use tobacco products, or with initiating NRT in an effort to decrease the number of cigarettes smoked before complete cessation (the “reduce to quit” method).[34] Initiating the nicotine patch before a quit attempt may be more effective than is applying the patch on the quit date. However, data are conflicting, and the evidence does not support using other forms of NRT before the quit date.[34] Precautions common to all forms of NRT include recent (≤2 weeks) myocardial infarction (MI), serious arrhythmia or angina pectoris, pregnancy, breast-feeding, and adolescence.[20]

Sustained-release bupropion

Sustained-release bupropion is an atypical antidepressant medication hypothesized to promote smoking cessation by blocking the reuptake of dopamine and norepinephrine in the central nervous system[4] and possibly by acting as a nicotine receptor antagonist.[35] These neurochemical effects are believed to modulate the dopamine reward pathway and reduce cravings for nicotine and symptoms of withdrawal.[4] When compared to placebo, sustained-release bupropion increases the long-term abstinence rate with a risk ratio (RR) of 1.64.[36] Bupropion's tobacco-cessation efficacy is similar to

that of NRT.[36] Sustained-release bupropion carries a boxed warning for suicidal ideation, as do other antidepressants. It is contraindicated in seizure disorder, current or past anorexia or bulimia, monoamine oxidase inhibitor use within 14 days, concomitant use of other forms of bupropion, and simultaneous abrupt discontinuation of alcohol, sedatives, or antiepileptic medications.[37]

Varenicline

Varenicline is a partial agonist that binds with high affinity and selectivity at $\alpha_4\beta_2$ neuronal nicotinic acetylcholine receptors.[38] The efficacy of varenicline in smoking cessation is believed to be the result of sustained, low-level agonist activity at the receptor site combined with competitive inhibition of nicotine binding. The partial agonist activity induces modest receptor stimulation, leading to increased dopamine levels, which attenuates the symptoms of nicotine withdrawal. In addition, by blocking the ability of nicotine to activate $\alpha_4\beta_2$ nicotinic acetylcholine receptors, varenicline inhibits the surges of dopamine release that are believed to be responsible for the reinforcement and reward associated with smoking.[38] Use of varenicline more than doubles the chances of quitting when compared to placebo, and it is superior to bupropion or NRT.[36,39] Patients should be monitored for neuropsychiatric symptoms, including changes in behavior, mood, or suicidal thoughts and behavior.[40]

PHARMACOTHERAPY FOR TREATING TOBACCO USE AND DEPENDENCE

Transdermal Nicotine Patch

CASE 91-1

QUESTION 1: T.B. is a 32-year-old female who is enrolled in a worksite smoking-cessation program. During the previous group session, the cessation counselor discussed the various medications for cessation. T.B. has set her quit date for 1 week from today, and she is interested in starting the nicotine transdermal patch. She is currently smoking 1.5 packs per day (PPD), which is a reduction from the two PPD she had been smoking for the past 10 years. T.B. reports she smokes several cigarettes in succession immediately after waking in the morning. She takes no medications and has no medical problems.

Which nicotine transdermal product should T.B. select, and how should it be used?

Transdermal nicotine delivery systems consist of an impermeable surface layer, a nicotine reservoir, an adhesive layer, and a removable protective liner. Although the transdermal delivery technology varies by manufacturer, nicotine is well absorbed, with 68% to 82% of the dose released from 24-hour patch formulations systemically bioavailable across the skin. Plasma nicotine concentrations from the patch rise slowly during 1 to 4 hours and peak within 3 to 12 hours after application.[11] Levels of nicotine achieved with the transdermal patch are lower and fluctuate less than do those achieved with tobacco products or other NRT formulations (see Fig. 91-2).

The transdermal nicotine patch exhibits significantly improved abstinence rates relative to placebo.[4] A systemic review of 51 trials with nicotine patch versus placebo found an RR of 1.64 with at least 6 months of follow-up.[31]

DOSING

The manufacturers' recommended dosages are listed in Table 91-4. In general, higher levels of smoking necessitate the use of higher strength formulations and a longer duration of therapy. Ultimately, the starting dose, rate of tapering, and total duration of therapy must be individualized to the patient's baseline smoking levels, development of side effects (eg, nausea, dyspepsia, nervousness, dizziness, and sweating), and the presence or absence of withdrawal symptoms. T.B. currently smokes 30 cigarettes per day, and thus she should initiate the regimen using the 21-mg per day patch.

PATIENT EDUCATION

T.B. should be instructed to apply the patch to a clean, dry, hairless area of skin on the upper body or the upper outer part of her arm at approximately the same time each day. To minimize the potential for local skin reactions, the patch application site should be rotated daily, and the same area should not be used again for at least 1 week. After patch application, T.B. should ensure that the patch adheres well to the skin, especially around the edges. The clinician should reassure T.B. that water will not reduce the effectiveness of the nicotine patch if it is applied correctly, and she may bathe, shower, swim, or exercise while wearing the patch. Finally, T.B. should be advised to discontinue use of the nicotine patch and contact a health care provider if skin redness caused by the patch does not resolve after 4 days; if the skin swells or a rash develops; if irregular heartbeat or palpitations occur; or if she experiences symptoms of nicotine overdose such as nausea, vomiting, dizziness, diarrhea, sweating, weakness, or rapid heartbeat.

ADVERSE REACTIONS

Case 91-1, Question 2: Ten days later, T.B. calls to report an itchy rash that she believes is caused by the nicotine patch. She noticed the rash yesterday when she removed the first patch from her left upper arm. This morning, after removing the second patch from her right upper arm, she noticed a similar rash. T.B. describes the skin on her right arm as slightly red, but not swollen; the rash on her left arm has only a faint trace of pink discoloration. Her last cigarette was 2 days ago. How should T.B. be managed at this time?

The most common side effects associated with the nicotine patch are local reactions (erythema, burning, and pruritus) at the skin application site. These reactions are generally caused by skin occlusion or sensitivity to the patch adhesives. Rotating the patch application sites daily minimizes skin irritation; nonetheless, skin reactions to the patch adhesives occur in up to 50% of patch users. Fewer than 5% of patients discontinue therapy because of a skin reaction.[4]

T.B. appears to be experiencing a mild skin reaction and should be reassured that it is common for the skin to appear erythematous for up to 24 to 48 hours after the patch is removed. T.B. can apply topical hydrocortisone cream (0.5% or 1%) or triamcinolone cream (0.5%) for symptomatic treatment.[4] Another option would be to try a different brand of patch because the adhesive may vary. Because the rash on her left arm has nearly resolved, it is reasonable for T.B. to continue using the nicotine transdermal patch provided that the erythema is not too bothersome.

Other less common side effects associated with the transdermal nicotine patch include vivid or abnormal dreams, insomnia, and headache. Sleep disturbances likely result from nocturnal nicotine absorption. Patients experiencing troublesome sleep disturbances should be instructed to remove the patch before bedtime and apply a new patch as soon as possible after waking the following morning.[4,20]

The clinician should also provide behavioral counseling support by asking T.B. about the current quit attempt. Appropriate issues to address include her confidence in remaining tobacco free, situations in which she has been tempted to smoke and potential triggers for relapse, nicotine withdrawal symptoms, her social support system for quitting, and any other questions or concerns she might have. It is reasonable to review potential coping strategies (behavioral and cognitive; see Table 91-3) and schedule a future follow-up call. The clinician should commend T.B. for her decision to quit, congratulate her for remaining free of cigarettes for 48 hours, and reassure her that skin irritation is a common, yet generally manageable, complication with the nicotine patch.

PRODUCT SELECTION CONSIDERATIONS

The primary advantage of the transdermal nicotine patch compared with other NRT formulations is that the patch is easy to use, releases a continuous dose of nicotine throughout the day, and requires administration only once daily. Disadvantages of the patch include a high incidence of skin irritation associated with the patch adhesives and the inability to acutely adjust the dose of nicotine to alleviate

symptoms of withdrawal. Finally, patients with underlying dermatologic conditions (eg, psoriasis, eczema, or atopic dermatitis) should not use the patch because they are more likely to experience skin irritation.[4]

Case 91-1, Question 3: T.B. would like to discontinue the nicotine transdermal patch. She would like to purchase a nonprescription smoking-cessation medication and wants to know whether the gum or lozenge is an effective alternative. What options would you recommend? What factors should be considered?

Nicotine Gum

Nicotine polacrilex gum is a resin complex of nicotine and polacrilin in a chewing gum base that provides slow release and absorption of nicotine across the oral mucosa. The product is available in 2- and 4-mg strengths, and in multiple flavors. The gum has a distinct, tobacco-like, slightly peppery, minty, or fruity taste and contains buffering agents to increase the salivary pH, which enhances the buccal absorption of nicotine. The amount of nicotine absorbed from each piece is variable, but when used properly, ~1.6 and 2.2 mg of nicotine is absorbed from each 2- and 4-mg piece of gum, respectively.[11] Peak plasma concentrations of nicotine are achieved ~30 minutes after chewing a single piece of gum and then slowly decline thereafter (see Fig. 91-2). Patients using nicotine gum are significantly more likely to remain abstinent compared with those receiving placebo, with an RR of 1.49 versus placebo.[4,31]

DOSING

Table 91-4 outlines the manufacturers' recommended dosing schedule for the nicotine gum. The recommended dosage of the nicotine gum is based on the "time to first cigarette" (TTFC) of the day. Having a strong desire or need to smoke soon after waking is viewed as a key indicator of nicotine dependence.[20,41] Therefore, patients who smoke their first cigarette of the day within 30 minutes

of waking are likely to be more highly dependent on nicotine and require higher dosages than do those who delay smoking for >30 minutes after waking (see Table 91-4). The “chew and park” method allows for the slow, consistent release of nicotine. Patients can use additional pieces of gum (to the daily maximum of 24 pieces per day) if cravings occur between scheduled doses. In general, patients who smoke a greater number of cigarettes per day will require more nicotine gum to alleviate their cravings than will patients who smoke fewer cigarettes per day. It is preferable to use the gum on a fixed schedule of administration, tapering during 1 to 3 months rather than using it only as needed to control cravings.[4,20]

PATIENT EDUCATION

Proper chewing technique is crucial when using the nicotine gum, using the “chew and park” method (see Table 91-4). The chew and park steps should be repeated until most of the nicotine is extracted; this generally occurs after 30 minutes and becomes obvious when chewing no longer elicits the characteristic taste or tingling sensation.

Patients should be warned that the absorption and, therefore, the effectiveness of nicotine gum might be reduced by acidic beverages (eg, coffee, juices, wine, and soft drinks), which transiently reduce the salivary pH.[42] To prevent this interaction, patients should be advised not to eat or drink (except water) for 15 minutes before or while using the nicotine gum.

ADVERSE REACTIONS

Most of the common side effects can be minimized or prevented using proper chewing technique.[4,20] Patients should be warned that chewing the gum too rapidly may result in excessive release of nicotine, leading to lightheadedness, nausea, vomiting, irritation of the throat and mouth, hiccups, and indigestion.

PRODUCT SELECTION CONSIDERATIONS

Advantages of nicotine gum include the fact that this formulation may be used to satisfy oral cravings and the 4-mg strength might delay weight gain.[4] For these reasons, the gum may be particularly beneficial for patients who have weight gain concerns or for patients who report boredom as a trigger for smoking. The gum might also be advantageous for patients who desire flexibility in dosing and prefer the ability to self-regulate nicotine levels to manage withdrawal symptoms. Some patients may find that the viscous consistency of the gum makes it difficult to use because it sticks to dental work. Others may find it difficult or socially unacceptable to chew the gum so frequently. Nicotine gum should not be used by patients with temporomandibular joint (TMJ) conditions or if it may interfere with dental work.

Nicotine Lozenge

The nicotine polacrilex lozenge is a resin complex of nicotine and polacrilin in a sugar-free, flavored lozenge. The product is available in 2- and 4-mg strengths, which are meant to be consumed like hard candy or other medicinal lozenges (eg, sucked and moved from side to side in the mouth until fully dissolved). A mini-lozenge is also available. Because the nicotine lozenge dissolves completely, it delivers ~25% more nicotine than does an equivalent dose of nicotine gum.[31] Similar to the nicotine gum, the lozenge also contains buffering agents (sodium carbonate and potassium bicarbonate) to increase salivary pH, thereby enhancing buccal absorption of the nicotine. Peak nicotine concentrations of nicotine with the lozenge are achieved after 30 to 60 minutes of use and then slowly decline thereafter (see Fig. 91-2). The nicotine lozenge increases 6-month abstinence rates by about 50% compared with placebo.[31]

DOSING

Table 91-4 outlines the manufacturers' recommended dosing schedule for the nicotine lozenge. Similar to the nicotine gum, the

lozenge is dosed based on the TTFC. Patients are more likely to succeed if they use the lozenge on a fixed schedule rather than as needed. Patients can use additional lozenges (up to 5 lozenges in 6 hours or a maximum of 20 lozenges per day) if cravings occur between scheduled doses.

PATIENT EDUCATION

Similar to the gum, the nicotine lozenge is a specially formulated nicotine delivery system that must be used properly for optimal results. The lozenge should be allowed to dissolve slowly in the mouth; when nicotine is released, a warm, tingling sensation may be experienced. The patient should occasionally rotate the lozenge to different areas of the mouth to reduce the potential for mucosal irritation. When used correctly, the lozenge should completely dissolve within 30 minutes. Patients should be counseled not to chew or swallow the lozenge because this increases the incidence of gastrointestinal-related side effects.

As with the gum, patients should be cautioned that the effectiveness of the nicotine lozenge may be reduced by acidic beverages such as coffee, juices, wine, or soft drinks.[20] Patients should be advised not to eat or drink (except water) for 15 minutes before or while using the nicotine lozenge.

ADVERSE REACTIONS

In general, the nicotine lozenge is well tolerated. The most common side effects include nausea, hiccups, cough, dyspepsia, headache, and flatulence. Patients who use more than one lozenge at a time, continuously use one lozenge after another, or chew or swallow the lozenge are more likely to experience dyspepsia or hiccups.

PRODUCT SELECTION CONSIDERATIONS

The nicotine lozenge is similar to the nicotine gum formulation in that it may be used to satisfy oral cravings, the 4-mg strength might delay weight gain, and patients can self-titrate therapy to acutely manage withdrawal symptoms.[4] Because the lozenge does not require

chewing, many patients find this to be a more discreet nicotine delivery system. The disadvantages of the lozenge are the fact that it requires frequent dosing, and the gastrointestinal side effects (nausea, hiccups, and heartburn) may be bothersome.

T.B. has expressed interest in either the nicotine gum or lozenge formulation for her quit attempt. Both agents are effective, and the choice of therapy is dependent on the patient's preferences, including the ability to comply with the regimen, previous experience with cessation medications, and other concerns (eg, adverse effects, weight gain, and cost of medications). T.B. would be a candidate for either agent provided she is able to comply with the frequent dosing schedule (one lozenge or piece of gum every 1–2 hours while awake). T.B. smokes her first cigarette of the day immediately after waking in the morning, and she smokes ~30 cigarettes per day; this smoking pattern suggests a higher degree of nicotine dependence, and therefore T.B. would benefit from a higher dose of NRT. T.B. should initiate treatment with the 4-mg strength of either the nicotine lozenge or nicotine gum dosed every 1 to 2 hours while she is awake and tapered according to the schedule outlined in Table 91-4.

Postcessation Weight Gain

Case 91-1, Question 4: T.B. is very concerned about gaining weight after she quits smoking. Is weight gain common after quitting, and if so, how can this be prevented?

Most tobacco users gain weight after quitting, and clinicians should neither deny the likelihood of weight gain nor minimize its significance.[4,43] For nearly all patients, the health risks associated with postcessation weight gain are negligible compared with the risks of continued smoking.

After 12 months of abstinence from smoking, a mean increase of 4 to 5 kg in body weight is most common, with most weight gain occurring within three months of quitting. There is a high level of variability in observed weight change.[43]

Although weight gain with tobacco cessation is well established, the mechanism is unclear. Nicotine is an appetite suppressant and may increase metabolism. The increased appetite that occurs with tobacco cessation coupled with decreased metabolism may contribute to weight gain. Furthermore, evidence suggests that nicotine increases the basal metabolic rate, and removal of this effect results in a decline in energy expenditure at a time when appetite is increased.[43] Increased postcessation caloric intake might also result from an improved sense of taste or a change in the hand-to-mouth ritual through the substitution of tobacco with food.

In general, a patient is less likely to be successful if he or she attempts to change multiple behaviors at once. For most patients, strict dieting to prevent weight gain, especially during the early stages of quitting, is generally not recommended and is ineffective.[4,44] T.B. should be counseled that the average weight gain of <10 pounds (4.54 kg) is less detrimental to her overall health than is continuing to smoke. Although exercise interventions have not been shown to reduce weight gain among quitters,[44] it should not be ruled out as a recommendation for T.B. because she expresses significant concern about weight gain, and this might be a barrier to her quitting. Modest increases in activity can help with weight gain, and exercise can serve as a behavioral substitution for tobacco use while enhancing overall well-being. Furthermore, T.B. should be advised to plan her meals in advance to avoid binge eating, increase her water intake to create a feeling of fullness, chew sugarless gum, and limit alcohol consumption. T.B. may consider pharmacotherapy options that have been shown to delay weight gain including NRT, varenicline, or sustained-release bupropion.[4,44] It is important to note, however, that none of the medications have been shown to prevent weight gain in the long term.[4,44]

Relapse to Smoking

Case 91-1, Question 5: During a follow-up contact, the clinician learns that T.B. smoked half a pack of cigarettes at a party over the weekend, and has

relapsed to her previous smoking levels after not having smoked for more than a month. How should the clinician respond?

The clinician should thank T.B. for being honest about her smoking, and ask whether she is comfortable discussing the circumstances during which the smoking occurred. At the time of her smoking, where was she, who was she with, how did she get access to cigarettes, and how was she feeling at the time? What, specifically, were the triggers for her relapse (eg, alcohol, depression, or friends who were smoking around her)? It is important that the clinician help the patient to use this information as part of the learning process, but it also is important to focus on the "positive," such as T.B.'s ability to have remained tobacco free for >1 month. Four weeks after quitting, most physical effects of nicotine withdrawal have completely resolved, and, thus, the relapse trigger for T.B. likely was psychological or situational, and could be abated through the application of effective coping techniques. After an informative discussion about the situation in which the smoking occurred, it is important that the clinician works with the patient in identifying strategies for avoiding relapse in the future (Table 91-3).

Smoking and Cardiovascular Disease

CASE 91-2

QUESTION 1: P.J. is a 62-year-old male admitted for a coronary artery bypass graft (CABG) surgery. His medical history is significant for angina, hypertension, dyslipidemia, peripheral vascular disease (PVD), and allergic rhinitis. He underwent a bilateral carotid endarterectomy procedure 2 years ago and had iliac artery angioplasty with stent placement 5 years ago for PVD. P.J.'s social history is significant for tobacco use (two PPD) and alcohol (three to four drinks per day). He is ~20 pounds (9.07 kg) overweight. His preoperative laboratory results are significant for a total cholesterol of 270 mg/dL (desirable, >200), low-density lipoprotein cholesterol (LDL-C) of 163 mg/dL (optimal, >70), high-density lipoprotein cholesterol (HDL-C) of 35 mg/dL (low, >40), and triglycerides of 350 mg/dL (normal, >150). His medications before admission include atenolol 50 mg daily, aspirin 81 mg daily, isosorbide dinitrate 20 mg tid, atorvastatin 20

mg daily, fluticasone nasal spray (50 µg per spray) one spray per nostril daily, and nitroglycerin 0.4 mg sublingually as needed.

Which of P.J.'s chronic medical conditions may be caused or exacerbated by his tobacco use?

A wealth of evidence suggests that cigarette smoking is a major cause of cardiovascular disease and is responsible for ~128,000 premature cardiovascular-related deaths each year.[3]

There are numerous plausible pathophysiologic mechanisms by which tobacco smoking contributes to the development of cardiovascular disease.[3,4] Oxidant gases and other compounds in tobacco smoke are believed to induce a hypercoagulable state characterized by increased platelet aggregation and thrombosis, which substantially increases the risk of MI and sudden death.[45,46] The carbon monoxide in smoke reduces the amount of oxygen available to tissues and organs, including myocardial tissue, and may reduce the ventricular fibrillation threshold.[45] Smoking may accelerate atherosclerosis through effects on serum lipids; smokers tend to have higher levels of total cholesterol, LDL-C, and triglycerides and lower HDL-C than do nonsmokers.[2] Smoking increases the levels of inflammatory mediators (C-reactive protein, leukocytes, and fibrinogen), which might contribute to the development and progression of atherosclerosis.[47] Finally, smoking stimulates the release of neurotransmitters (eg, epinephrine and norepinephrine) that increases myocardial workload and induces coronary vasoconstriction, leading to ischemia, arrhythmias, and sudden death.[2,45]

P.J.'s hospital admission for a CABG procedure for CHD and angina, and previous procedures for PVD (angioplasty with stent placement) and cerebrovascular disease (bilateral carotid endarterectomy) are all conditions associated with chronic tobacco use. His elevated total cholesterol, LDL-C, and triglycerides, and reduced HDL-C levels are consistent with smoking-induced dyslipidemia. Cigarette smoking, in combination with P.J.'s other established cardiovascular risk factors (hypertension and dyslipidemia), has synergistically increased his risk of serious

cardiovascular disease. Fortunately, the effects of smoking on lipids, coagulation, myocardial workload, and coronary blood flow appear to be reversible, and P.J.'s risk of developing further cardiovascular-related complications will markedly decrease if he is able to quit smoking.[2] Smoking cessation is associated with a 36% reduction in the risk of death among patients with established CHD. The reduced mortality risk associated with quitting smoking is comparable to that observed with other established secondary preventative approaches such as therapies for hyperlipidemia and hypertension.[48] The clinician should approach this hospitalization as an opportunity to assist P.J. with quitting smoking. Published data suggest that initiation of intensive cessation counseling interventions for hospitalized patients is effective in achieving long-term abstinence.[49]

Noncigarette Forms of Tobacco

Case 91-2, Question 2: The cardiothoracic surgeon has strongly advised P.J. to quit smoking. Will cutting down to one to two cigars per day be an acceptable alternative to his current cigarette use?

The adverse health effects of cigar smoking include oral cancer, esophageal cancer, pancreatic cancer, laryngeal cancer, lung cancer, CHD, and aortic aneurysm.[50] In addition, daily cigar smokers have increased all-cause mortality risk, and an increased risk of dying from chronic obstructive pulmonary disease (COPD).[51] Cigar smokers who report that they do not inhale still have increased risk of oral, laryngeal, and esophageal cancers.[50] Although the risk of daily cigar smoking is lower than that with cigarettes, it is significantly higher than that of nonsmokers, so the goal should be complete cessation of all tobacco products. Cigar weight and nicotine content vary widely from brand to brand and from cigar to cigar. Cigars range in weight from about 1 to 22 g, whereas a typical cigarette weighs <1 g. The nicotine content of 10 commercially available cigars studied in 1996 ranged from 10 to 444 mg. In comparison, U.S. cigarettes have a relatively narrow total nicotine content range (mean, 13.5 ± 0.1 mg)

per cigarette.[52] It is possible for one large cigar to contain as much tobacco as an entire pack of cigarettes and to deliver enough nicotine to establish and maintain dependence.[20,53]

The amount of nicotine delivered by one to two cigars per day is capable of sustaining his dependence on nicotine. Furthermore, former cigarette smokers are more likely to inhale deeply, which further increases the risk of cancer and cardiovascular and pulmonary disease. The clinician should strongly advise P.J. to quit smoking cigarettes and that switching to cigars is not a safe alternative.

Case 91-2, Question 3: P.J. is willing to quit completely, but he is worried because he has tried to quit smoking "hundreds of times" and has never been able to quit for longer than 1 week. He expresses a desire for a medication to assist him during this quit attempt. He has tried the nicotine gum and transdermal patch during three previous quit attempts. He did not like the gum because it made his jaw sore. He had temporary success with the nicotine patch, but found it to be less flexible than was the gum. For example, when he needed extra nicotine during stressful situations, he could not apply a second patch. What treatment alternatives are reasonable for P.J.?

P.J. has inadequately responded to treatment with the transdermal patch, and experienced intolerable jaw soreness with the nicotine gum. Newer formulations of the nicotine gum are less viscous, and therefore easier to chew, than were earlier formulations of the gum; however, other options are available. First-line treatment options that he has not tried include the nicotine lozenge (see Case 91-1, Question 3), nicotine nasal spray, nicotine inhaler, sustained-release bupropion, varenicline, or an effective combination of first-line agents (see Case 91-3, Question 1).

Nicotine Nasal Spray

The nicotine nasal spray is an aqueous solution of nicotine available in a metered spray pump for administration to the nasal mucosa. Nicotine in the nasal spray is more rapidly absorbed than are other NRT formulations (see Fig. 91-2), with peak venous nicotine

concentrations achieved within 11 to 18 minutes of administration.[54] Use of the nicotine nasal spray more than doubles long-term abstinence rates when compared with placebo.[31]

DOSING

Table 91-4 outlines the manufacturers' recommended dosing schedule for the nicotine nasal spray. A dose of nicotine (1 mg) is administered as two sprays, one (0.5-mg spray) in *each* nostril. For best results, patients should be encouraged to use at least eight doses per day during the initial 6 to 8 weeks of therapy because less frequent administration may be less effective. The initial regimen may be increased, as needed, to a maximum recommended dosage of five doses per hour or 40 mg daily. After 6 to 8 weeks, the dose should be gradually decreased during an additional 4 to 6 weeks.

PATIENT EDUCATION

Before using the nasal spray for the first time, the nicotine nasal spray pump must be primed by actuating the device into a tissue until a fine spray is visible (about six to eight times). When administering a dose, the patient should tilt the head back slightly and insert the tip of the bottle into the nostril as far as is comfortable. After actuation of the pump, the patient should not sniff, swallow, or inhale through the nose because this increases the irritant effects of the spray. The spray increases the likelihood of tearing, coughing, and sneezing, so patients should wait 5 minutes before driving or operating heavy machinery.

ADVERSE REACTIONS

Most patients report moderate-to-severe nasal irritation during the first 2 days of therapy, but most become tolerant to the irritant effects during the first week. Nasal congestion and transient changes in taste and smell have also been reported.[4] Despite the high incidence of local adverse effects (see Table 91-4), most patients become tolerant to the irritant effects of the spray.

PRODUCT SELECTION CONSIDERATIONS

The primary advantage in using the nicotine nasal spray is the ability to rapidly titrate therapy to manage withdrawal symptoms. However, because nicotine from the spray more rapidly penetrates the central nervous system, developing dependence may be more likely. The nicotine nasal spray has a dependence potential intermediate between tobacco products and other NRT products. Individuals with chronic nasal disorders (eg, rhinitis, polyps, and sinusitis) or severe reactive airway disease should not use the nicotine nasal spray because of its irritant effects and potential to cause an asthma exacerbation.[4,20] Disadvantages of nicotine nasal spray include higher cost than that of the patch, gum, or lozenge, and being available only with a prescription.

Nicotine Inhaler

The nicotine oral inhaler consists of a plastic mouthpiece and a disposable cartridge with a porous plug containing 10 mg of nicotine and 1 mg of menthol. The typical pack-a-day smoker repeats the hand-to-mouth motion up to 200 times daily, so it is not surprising that many smokers find they miss the physical manipulation of the cigarette and associated behaviors that accompany smoking. The nicotine inhaler was designed to provide nicotine replacement in a manner similar to smoking while addressing the sensory and ritualistic factors that are important to many patients who smoke.

As a patient inhales through the mouthpiece, nicotine vapor releases from the cartridge and distributes throughout the oral cavity. When the inhaler is used correctly, the cartridge releases ~4 mg of nicotine vapor, and 2 mg is absorbed across the buccal mucosa.[55] Peak plasma nicotine concentrations are achieved after ~30 minutes of use and then slowly decline[11] (see Fig. 91-2). Use of the nicotine inhaler approximately doubles long-term abstinence rates when compared with placebo (see Table 91-4).[31]

DOSING

Table 91-4 outlines the manufacturers' recommended dosing schedule for the nicotine inhaler. During the initial 3 to 6 weeks of treatment, the patient should use 1 cartridge every 1 to 2 hours while awake. This should be increased, as needed, to a maximum of 16 cartridges per day. The manufacturer recommends that each cartridge be depleted of nicotine by frequent continuous puffing for 20 minutes. The recommended duration of treatment is 3 months, after which patients may be weaned from the inhaler by gradual reduction of the daily dose during the following 6 to 12 weeks.

PATIENT EDUCATION

To minimize the likelihood of throat irritation, patients should be instructed to inhale shallowly (as if puffing a pipe). The inhaler should be used with continuous shallow puffs for 20 minutes.[20] The release of nicotine from the inhaler is temperature dependent and significantly reduced at temperatures <40 °F (4.44 °C).[4,20] Under cold conditions, patients should store the inhaler and cartridges in a warm place (eg, inside pocket).[4] Conversely, more nicotine is released under warmer conditions, although nicotine plasma concentrations achieved using the inhaler in hot climates at maximal doses will not exceed levels normally achieved with smoking.[33]

As with all forms of NRT that are absorbed across the buccal mucosa, the effectiveness of the nicotine inhaler is reduced by acidic foods and beverages, such as coffee, juices, wine, or soft drinks. Therefore, patients should be instructed not to eat or drink anything (except water) for 15 minutes before or while using the inhaler.[20]

ADVERSE REACTIONS

The most common side effects associated with the nicotine inhaler include mouth or throat irritation (40%) and cough (32%) that usually decrease with continued use.[4] Less common side effects are rhinitis, dyspepsia, hiccups, and headache. Adverse reactions necessitating discontinuation of treatment occurred in <5% of patients using the inhaler.

PRODUCT SELECTION CONSIDERATIONS

Patients who express a preference for therapy that can be easily titrated to manage withdrawal symptoms or one that mimics the hand-to-mouth ritual of smoking may find the nicotine inhaler to be an appealing option. Patients with underlying bronchospastic conditions should use the nicotine inhaler with caution because the nicotine vapor can be irritating and might induce bronchospasm. Nicotine inhalers require a prescription and are more expensive than are nonprescription NRT products.

Sustained-Release Bupropion

The antidepressant, bupropion, may be beneficial for patients who are attempting tobacco cessation (see Table 91-4). In a systematic review, sustained-release bupropion was shown to increase long-term abstinence rates relative to placebo (RR 1.640) and demonstrated similar efficacy to NRT (RR 0.99).[36]

DOSING

Because ~1 week of treatment is necessary to achieve steady-state blood levels, sustained-release bupropion should be initiated while the patient is still smoking (Table 91-4). Patients should set a target quit date that falls within the first 2 weeks of treatment, generally in the second week. The starting dose of sustained-release bupropion is one 150-mg tablet each morning for the first 3 days. If the initial dose is tolerated, the dosage should be increased to the recommended maximal dosage of 300 mg daily (150 mg bid). Therapy should be continued for up to 12 weeks after the quit date.[4,20]

PATIENT EDUCATION

Patients experiencing insomnia should avoid taking the second dose close to bedtime. Patients should be informed that bupropion might cause dizziness or drowsiness and should exercise caution when driving or operating machinery. Patients should avoid alcohol, or

drink only in moderation while taking bupropion because alcohol use can increase the risk of seizures. Abrupt cessation of alcohol use while taking bupropion might increase the risk of seizure.[4,20,37]

ADVERSE REACTIONS

The most common adverse effects associated with bupropion therapy include insomnia (35%–40%) and dry mouth (10%).[56] These usually lessen with continued use. Taking the second daily dose in the early evening, but no sooner than 8 hours after the first dose, might reduce insomnia. Less common side effects include headache, nausea, tremors, and rash. Seizures are a dose- related toxicity associated with bupropion therapy. For this reason, bupropion is contraindicated in patients with underlying seizure disorders and in those undergoing abrupt discontinuation of alcohol, benzodiazepines, barbiturates, or antiepileptic medications. Bupropion also is contraindicated in patients with a current or prior history of anorexia or bulimia nervosa and those who are taking monoamine oxidase inhibitors. Bupropion should be used with extreme caution in patients with a history of seizures or cranial trauma, in individuals taking medications that may lower the seizure threshold, and in patients with underlying severe hepatic cirrhosis. The manufacturer recommends that patients space the doses at least 8 hours apart and limit the total daily dose to no more than 300 mg. Bupropion is associated with significant neuropsychiatric adverse effects, including changes in mood, hallucinations, anxiety, and suicidal ideation.[37]

PRODUCT SELECTION CONSIDERATIONS

Sustained-release bupropion is an option for patients who prefer to take oral medications. (An alternative, varenicline, is described subsequently). Because sustained-release bupropion tablets require twice-daily administration, this agent may be preferable for patients with adherence concerns (eg, those unable to consistently use short-acting NRT formulations that require multiple daily doses). Sustained-release bupropion might be beneficial for use in patients

with coexisting depression or in individuals with a history of depressive symptoms during a previous quit attempt. Finally, sustained-release bupropion has been found to reduce postcessation weight gain during treatment,[4,44] and this might be of short-term benefit in patients with concerns about weight gain after quitting. Disadvantages of sustained-release bupropion include a high prevalence of insomnia and several contraindications and precautions mentioned earlier.

Varenicline

Varenicline significantly increases long-term abstinence rates relative to placebo, NRT, and sustained-release bupropion.[39,57,58] Varenicline is the most efficacious pharmacotherapy for tobacco cessation.[3,58] The pooled RR for long-term abstinence (≥6 months) for varenicline compared with placebo was 2.24 (95% confidence interval [CI], 2.06–2.43). The pooled RR for varenicline versus sustained-release bupropion at the 6-month follow-up was 1.39 (95% CI, 1.25–1.54). At 24 weeks, the pooled RR for varenicline compared to NRT was 1.25 (95% CI, 1.14–1.37).[39] Longer durations of varenicline for up to 12 months have been shown to be safe and effective in clinical trials.[39,59]

PHARMACOKINETICS

Varenicline absorption is virtually complete after oral administration, and oral bioavailability is unaffected by food. Once absorbed, varenicline undergoes minimal metabolism, with 92% excreted unchanged in the urine. Renal elimination is primarily through glomerular filtration, along with active tubular secretion.[59] The half-life is ~24 hours, and following administration of multiple oral doses, steady-state conditions are reached within 4 days.[40,59]

DOSING

Treatment with varenicline (see Table 91-4) should be initiated 1 week before the patient stops smoking. This dosing regimen allows

for gradual titration of the dose to minimize treatment-related nausea and insomnia. The recommended dosage titration for varenicline is as follows: 0.5 mg daily on days 1 to 3, 0.5 mg twice daily on days 4 to 7, and 1 mg twice daily on weeks 2 to 12. For patients who have successfully quit smoking at the end of 12 weeks, an additional course of 12 weeks may be considered to increase the likelihood of long-term abstinence.[40,60] In an alternative approach to smoking reduction, the patient should set a quit date 8 to 35 days after starting varenicline, then decrease their smoking by about 50% over the first 4 weeks, an additional 50% by the second 4 weeks, with the goal of being fully abstinent after 12 weeks. They should then continue varenicline for 12 additional weeks.[40,59]

Varenicline should be used with caution in patients with impaired renal function. For patients with severe renal dysfunction (estimated creatinine clearance <30 mL/minute), the recommended maximal dose of varenicline is 0.5 mg twice daily. In patients with end-stage renal disease undergoing hemodialysis, a maximal dose of 0.5 mg daily is recommended.[40,59] Varenicline has been shown to be effective at lower dosages with a lower incidence of adverse effects.[39]

PATIENT EDUCATION

Varenicline should be taken after eating and with 8 ounces of water. Nausea and insomnia are side effects that are usually temporary.[40] Patients should be advised to discontinue varenicline and contact their health care provider immediately if they experience agitation, hostility, depressed mood, or changes in behavior or thinking that are not typical for them (see adverse reactions subsequently).[40]

ADVERSE REACTIONS

Varenicline is generally well tolerated. Common side effects include nausea (30%), sleep disturbance (insomnia 18%; abnormal dreams 13%), constipation (8%), flatulence (6%), and vomiting (5%). Nausea is dose dependent and generally described as mild or moderate and often transient; however, for some patients, it persists for several

months. Initial dose titration was beneficial in reducing the occurrence of nausea. Approximately 3% of subjects receiving varenicline 1 mg bid discontinued treatment prematurely because of nausea. For patients with intolerable nausea, dose reduction should be considered.[59]

A large, randomized, controlled trial that included a cohort of smokers with current or past psychiatric disorders evaluated the neuropsychiatric safety of varenicline, bupropion, nicotine patch, and placebo. No difference in neuropsychiatric adverse events was reported between groups.[57] However, the FDA recommends that clinicians and patients monitor for changes in mood and behavior during treatment with varenicline.[40]

The prescribing information for varenicline includes a warning for a possible increased risk of cardiovascular events (in patients with underlying cardiovascular disease).[40] However, systematic review, meta- analysis, and a randomized clinical trial concluded that there is no significant increase in the risk of serious cardiovascular events with varenicline in tobacco cessation, including patients with a history of cardiovascular disease.[61–63] Seizures have been reported in patients treated with varenicline, most often within the first month of therapy. These events occurred in individuals who had no seizure history, as well as in those with a remote history or well-controlled seizure disorder. Varenicline should be used cautiously in patients with a history of seizures, or with any other factors that lower the seizure threshold.[40]

PRODUCT SELECTION CONSIDERATIONS

Varenicline is a first-line agent for the treatment of tobacco use and dependence.[4,58] It offers a convenient oral dosing regimen and a mechanism of action that might be particularly appealing for patients who have failed quit attempts with other first-line agents (eg, NRT or sustained-release bupropion). It has the highest efficacy of any of the tobacco-cessation pharmacotherapies. P.J. has tried the nicotine gum and transdermal patch during previous quit attempts. Because he was intolerant to the nicotine gum (sore jaw), this form of NRT is

not appropriate. P.J.'s experience with the transdermal patch suggests he may benefit from a short-acting NRT formulation that enables titration of doses as needed to alleviate symptoms of withdrawal and situational cravings. Other first-line therapies include the nicotine nasal spray, inhaler, and lozenge; sustained-release bupropion; or varenicline. P.J. should not use the nicotine nasal spray because he has allergic rhinitis and may be more susceptible to the irritant effects of the spray. Furthermore, the safety and efficacy of the nasal spray in patients with chronic nasal disorders have not been adequately studied. Reasonable choices for P.J. therefore include sustained-release bupropion, nicotine lozenge, nicotine inhaler, or varenicline. Any of these options are reasonable, and the choice of therapy should be dictated by P.J.'s individual preference. If varenicline is chosen, given P.J. has underlying cardiovascular disease, he should be instructed to notify a health care provider for new or worsening cardiovascular symptoms and to seek immediate medical attention if he experiences signs and symptoms of MI. Finally, it is reasonable to consider combination therapy (see Case 91-3, Question 1).

Safety of Nicotine Replacement Therapy Among Patients with Cardiovascular Disease

Case 91-2, Question 4: P.J. would like to try the nicotine inhaler. Is NRT safe for use in patients with cardiovascular disease?

Nicotine activates the sympathetic nervous system, leading to an increase in heart rate, blood pressure, and myocardial contractility. Nicotine also may cause coronary artery vasoconstriction. These known hemodynamic effects of nicotine have led to doubts about the safety of using NRT in patients with established cardiovascular disease, particularly those with serious arrhythmias, unstable angina, or recent MI.

Soon after the nicotine patch was approved, anecdotal case reports in the lay press linked NRT (patch and gum) with adverse cardiovascular events (eg, arrhythmias, MI, and stroke). Since then, several randomized, controlled trials evaluated the safety of NRT in patients with cardiovascular disease.[64,65] The results of these trials suggest no significant increase in the incidence of cardiovascular events or mortality among patients receiving the nicotine patch when compared with placebo. However, because these trials specifically excluded patients with unstable angina, serious arrhythmias, and recent MI, the manufacturers of NRT products recommend that these agents be used with caution among patients in the immediate (within 2 weeks) post-MI period, those with serious arrhythmias, and those with unstable angina.[4,20]

NRT use in patients with cardiovascular disease has been the subject of numerous reviews, and it is widely believed by experts in the field that the risks of NRT in this patient population are small in relation to the risks of continued tobacco use.[4,61,63,65] Although the use of NRT may pose some theoretic risk in a patient such as P.J., cigarette smoking is far more hazardous to his health. Cigarettes, unlike NRT, deliver numerous toxins that induce a hypercoagulable state, reduce the oxygen-carrying capacity of hemoglobin, and adversely affect serum lipids. The amount of nicotine that P.J. would receive using the recommended dose of any NRT product will not exceed the amount he previously obtained from his two PPD smoking habit. The clinician should strongly encourage pharmacotherapy during P.J.'s current quit attempt. P.J. is 10 pounds (4.54 kg) overweight; the additional risk imposed by a modest weight gain after smoking cessation likely will not be of clinical significance compared with that of continued smoking.

Combination Therapy for Tobacco Dependence

CASE 91-3

QUESTION 1: J.B. is a 60-year-old male referred to the pulmonary clinic for further evaluation and management of his COPD. He reports decreased exercise tolerance and has noted increasing shortness of breath (SOB) with minimal exertion (eg, while golfing or climbing stairs). He currently uses an albuterol inhaler (90 µg per puff), two puffs every 4 hours regularly for SOB. His medical history is otherwise unremarkable except for osteoarthritis controlled with acetaminophen 1 g tid. He has smoked ~1.5 to 2 PPD for >40 years. J.B. indicates he has made several quit attempts during the past year. On the first attempt (quitting "cold turkey"), J.B. relapsed within 2 days. J.B. successfully quit for nearly 2 weeks on his second attempt (using the 4-mg nicotine lozenge), but he found it difficult to adhere to the frequent dosing schedule and relapsed shortly after discontinuing the lozenge. His most recent quit attempt was 6 months ago using varenicline. After 1 month of abstinence, J.B. self-terminated varenicline (I thought I didn't need it anymore.) and relapsed within 1 week. On further questioning, J.B. states that he did not enroll in a behavioral counseling program or seek additional assistance (other than pharmacotherapy) during any of his quit attempts. He expresses an interest in smoking cessation but is discouraged by his prior lack of success. On physical examination, coarse breath sounds that clear after coughing are noted. A chest radiograph obtained in the office shows no infiltrates. J.B. is concerned about his worsening pulmonary function and is committed to making another effort to quit.

What treatment options are appropriate for J.B.?

Tobacco smoking is the single most important risk factor for the development of COPD, and almost all patients diagnosed with COPD are current or former smokers.[2,66] Given his escalating pulmonary symptoms, it is imperative that he stop smoking as soon as possible. J.B. should be advised that medications for COPD offer only limited symptomatic relief, and the most important component of his treatment is smoking cessation.[66,67] The clinician should commend J.B. for his interest in quitting and help him devise a patient-specific treatment plan.

Plasma levels of nicotine achieved with standard doses of NRT are generally much lower than are those attained with regular smoking.[54,68] As such, conventionally dosed NRT may deliver subtherapeutic nicotine levels for some individuals, and, in particular, for moderate-to-heavy smokers.

Combination NRT regimens, which typically consist of a long-acting agent (nicotine patch) in combination with a short-acting

formulation (ie, gum, lozenge, inhaler, or nasal spray), are options for initial therapy. The long-acting formulation, which delivers nicotine at a relatively constant level, is used to prevent the onset of severe withdrawal symptoms, and the short-acting formulation, which delivers nicotine at a more rapid rate, is used as needed to control withdrawal symptoms that may occur during potential relapse situations (eg, after meals, during times of stress, or when around other smokers).

Controlled trials suggest that the nicotine patch in combination with short-acting NRT formulations (ie, gum, lozenge, nasal spray, or inhaler) significantly increase quit rates relative to placebo.[31] The evidence regarding combination therapy with sustained-release bupropion and the nicotine patch is conflicting, although it is recommended in the guidelines.[36,69] Aggressive combination regimens including triple-agent NRT (eg, patch, inhaler, and nasal spray) with or without sustained-release bupropion, triple-combination therapy with patch, inhaler, and sustained-release bupropion[70] or varenicline, patch, and lozenge[71] may be a safe and effective treatment approach. Some data suggest that adding varenicline alone[72] or sustained-release bupropion and varenicline to nicotine patch[73,74] therapy may improve cessation rates; however, addition of sustained-release bupropion to varenicline had little effect on long-term abstinence and increased rates of depression and anxiety.[36,74]

Clinicians should be aware that although the combination of the nicotine patch and sustained-release bupropion has been approved by the FDA, the concurrent use of multiple NRT products is not FDA approved for tobacco cessation. Furthermore, the optimal agents, dosages, and durations of therapy for NRT combination therapy are currently unknown.

Given the severity of J.B.’s condition and his willingness to quit now, the clinician should initiate treatment as soon as possible. His treatment should consist of pharmacotherapy in conjunction with behavioral counseling and appropriate follow-up.

PHARMACOTHERAPY

The clinician should work with J.B. to select the most appropriate pharmacotherapy. As noted previously, appropriate options would include the various NRT formulations, sustained-release bupropion, varenicline, or an effective combination of first-line agents. For patients reporting a positive experience with a given medication, retreatment with the same agent or a combination of agents might be appropriate, with consideration given to increasing the dose, frequency, or duration of therapy. For patients reporting a negative experience with pharmacotherapy (eg, poor adherence, side effects, palatability issues, and cost), an alternative agent should be considered. Given J.B.'s previous adherence issues with the nicotine lozenge as monotherapy, it might be preferable to use a long-acting cessation medication such as the nicotine patch, sustained-release bupropion, or varenicline. Combination therapy might also be appropriate.

BEHAVIORAL COUNSELING

Although medications are effective alone in helping patients quit smoking, the combination with behavioral counseling maximizes patients' chances for a long-term, successful quit attempt. J.B.'s previous 1-month-long quit attempt highlights the success of varenicline in this patient; however, J.B.'s relapse likely is attributable to a shortened course of therapy and the absence of a behavioral change program. J.B. should be advised that the medications are designed to make patients more comfortable while quitting and that behavioral counseling is needed to address the "habit" of smoking by helping him cope with difficult situations and triggers for relapse. J.B. should be advised to pursue behavioral therapy options in addition to pharmacotherapy. J.B. should be reminded that adherence to the medication regimen—daily adherence, as well as duration of therapy—will increase his chances of quitting for good. Clinician-delivered counseling might also include a personalized message to further enhance his motivation to quit. For example, the clinician could perform pulmonary function testing and translate J.B.'s spirometry

results into an effective “lung age” (eg, the age of the average healthy individual with similar spirometry values). This educational approach has been found to significantly increase long-term (12-month) quit rates in a recent controlled trial.[75]

Drug Interactions With Smoking

CASE 91-4

QUESTION 1: M.K. is a new patient requesting Tri-Sprintec® (norgestimate/ethinyl estradiol). The new patient history form completed by M.K. reveals that she is 32 years old, weighs 143.30 pounds (64.86 kg), and is 70 inches (177.80 cm) tall. She takes no prescription medications, but occasionally uses loratadine 10 mg as needed for allergies, and ibuprofen 400 mg as needed for dysmenorrhea. She has no significant medical history. Her father has hypertension and suffered an MI last year. Her mother has type 2 diabetes and dyslipidemia. Her social history is significant for tobacco use (one PPD for 15 years), alcohol (one glass of wine every night), and caffeine (three to four cups of coffee daily).

Are there any potential drug interactions with M.K.’s new prescription?

SMOKING AND COMBINED HORMONAL CONTRACEPTIVES

One of the most important precautions to consider with oral contraceptive use is the potential interaction between tobacco smoke and estrogens in combination hormonal contraceptives (see Chapter 47, Contraception). Estrogens promote coagulation by altering clotting factor levels and increasing platelet aggregation. As described in Case 91-2, Question 1, substances present in tobacco smoke induce a hypercoagulable state, increasing the risk of acute cardiovascular events. Exposure to both factors (smoking and high levels of estrogen) greatly increases the risk of thromboembolic and thrombotic disorders. Considerable epidemiologic evidence indicates that cigarette smoking substantially increases the risk of adverse cardiovascular events, including stroke, MI, and thromboembolism in females who use oral combination hormonal contraceptives.[76,77] This risk is age related, in that the absolute risk of death as a result of cardiovascular disease in oral contraceptive users who smoke is

3.3/100,000 females, ages 15 to 34 years, compared with 29.4/100,000 females, ages 35 to 44 years. Because of the increased risk of adverse cardiovascular events, current guidelines[78] state that combination estrogen–progestin contraceptives should not be used in females who are older than 35 years of age and smoke, and progestin-only or nonhormonal contraceptives are recommended for use in this population. M.K. is 32 years of age, and despite smoking 20 cigarettes per day, oral contraceptive use is not contraindicated at this time. However, the clinician should strongly advise M.K. to quit smoking and assess her readiness to do so. M.K. should be informed that if she continues to smoke while using oral combined hormonal contraceptives, her risk of developing a blood clot, stroke, or heart attack will continue to increase with time.

ALTERNATIVE THERAPIES

Case 91-4, Question 2: Are e-cigarettes or vapes effective for smoking cessation?

Patients or clinicians may ask about the efficacy of ENDSs in tobacco cessation. These devices seem to offer a solution because they mimic smoking behaviors including hand-to-mouth movements, inhalation into airways, and exhalation of smoke-like aerosol. Some consider ENDS as a tool for harm reduction in cigarette smokers because they may reduce exposure to carcinogens and toxins in combustible tobacco cigarettes.[79] Current data is limited, but ENDS may help smokers successfully stop smoking.[79–81] More robust data on the safety and efficacy of ENDS are needed.[79,80] M.K. should be advised that although ENDS may be effective, more data support NRT, varenicline, and bupropion as cessation therapies.

Although many herbal and homeopathic products are available to help people quit smoking, data that support their safety and efficacy are lacking. Furthermore, patients should be cautioned that herbal cigarettes are not safe alternatives because they result in the inhalation of other toxins present in smoke.

CASE 91-4, QUESTION 3: M.K. is not considering quitting smoking in the next 30 days. She cannot discontinue her oral contraceptives because she is sexually active and needs a reliable form of birth control. Are low dose birth control pills or other formulations (eg patch or vaginal ring) safer for smokers?

Combined oral contraceptives available in the United States contain estrogen in doses ranging from 20 to 50 µg of ethinyl estradiol. Higher doses of ethinyl estradiol appear to have greater procoagulant effects.[82]

In 2001, the U.S. Surgeon General stated that lower dose oral contraceptives may be associated with a reduced risk of CHD compared with higher dose formulations. Despite this conclusion, the report cautioned that heavy smokers who use oral contraceptives still have a greatly elevated risk for CHD.[83]

Serum estrogen levels obtained with the vaginal ring are significantly lower than those achieved with either transdermal or oral combined contraceptive formulations, but data have not shown the patch or the ring to be safer options for females who smoke. Current guidelines apply the same precautions to all contraceptives containing estrogen.[83]

M.K.'s prescribed oral contraceptive agent (Tri-Sprintec®) contains 35 µg of ethinyl estradiol in combination with 0.25 mg norgestimate. Although some clinicians recommend the use of low-dose (20 µg) estrogen preparations in smokers, the available evidence suggests that the prescribed regimen poses no additional risk in M.K. The clinician should inform M.K. that there are currently no studies demonstrating a reduced risk of adverse cardiovascular events in smokers using oral contraceptives containing low doses (eg, 20 µg) of estrogen or the newer transdermal and vaginal ring formulations.[83] In the absence of published data, only smoking cessation can be advocated to definitively reduce the risk of stroke, MI, and thrombosis in females who use combined hormonal contraceptives.

BEHAVIORAL COUNSELING

Although M.K. is not considering quitting at this time, it is appropriate for the clinician to apply the 5 R's (see Table 91-2) to promote motivation to quit. This counseling should be *relevant* to M.K.'s situation and should highlight the *risks* of continued tobacco use, such as her elevated risk for thromboembolic and thrombotic disorders (associated with continued use of oral contraceptives). M.K. should be asked to think about the *rewards* of quitting and any potential *roadblocks* to quitting. At subsequent encounters, the clinician should sensitively assess M.K.'s tobacco use status and motivation to quit and offer assistance with quitting when M.K. is ready. If M.K. decides to quit, it would be important to reassess her caffeine intake because caffeine, which is metabolized via CYP450 1A, levels have been reported to increase by 56% in patients who quit smoking.[18]

Brief Interventions to Promote Tobacco Cessation

CASE 91-5

QUESTION 1: J.C. is a 52-year-old male with a history of asthma requesting a refill of his albuterol inhaler prescription. This is the third request for an albuterol inhaler (200 doses per inhaler) during the past 2 months. Before this period, his last refill was more than a year ago. J.C. reports that he has been using albuterol on most days of the week for coughing and SOB. He has no other medical conditions and takes no other medications. His social history is significant for tobacco use (smokes 1.5 PPD; he recently started smoking again after starting a new job where "everyone smokes"). J.C. previously quit smoking 20 years ago using the "cold turkey" approach (eg, no medications or counseling), and although he was successful, he was miserable for weeks; he expresses reluctance to "go through this again" during a stressful job transition.

The clinician is running behind schedule and does not have the time to provide comprehensive smoking-cessation counseling during this patient encounter.

What brief smoking-cessation interventions can the clinician provide to J.C. to assist him with quitting?

TELEPHONE QUITLINES

Clinicians should become aware of local, community-based resources for tobacco cessation, including telephone quitlines. When time or expertise does not afford provision of comprehensive tobacco- cessation counseling during a patient visit, clinicians are encouraged to apply a truncated 5 A's model, whereby they *ask* about tobacco use, *advise* tobacco users to quit, and *refer* patients who are ready to quit to a telephone quitline. Effective brief interventions can generally be accomplished in <3 minutes. Telephone services provide low-cost interventions that can reach patients who might otherwise have limited access to medical treatment because of geographic location or lack of insurance or financial resources. Data support the efficacy of quitline counseling in promoting abstinence.[26,28] The addition of medication to quitline counseling significantly improves abstinence rates compared with medication alone.[4] In addition, evidence suggests that quitlines are also effective for smokeless tobacco cessation.[84] The telephone number for the toll-free tobacco quitline is 1-800-QUIT NOW.

J.C.'s asthma is not well controlled (eg, increased use of short-acting bronchodilator). The change in J.C.'s asthma control is temporally related to his recent job change and relapse to daily smoking. Exposure to tobacco smoke is a potent trigger for asthma exacerbations and an important cause of poor asthma control. Given that the clinician is unable to provide comprehensive smoking-cessation counseling at this time, a brief intervention is appropriate. The clinician should strongly advise J.C. to quit as a key component of his asthma management plan, and refer him to a telephone quitline or to other resources that are available within the community (eg, local individual or group counseling programs). The clinician should briefly explain that pharmacologic treatment combined with support should increase the likelihood of a successful quit attempt compared to his previous, "cold turkey" experience. The clinician could address J.C.'s previous negative experience with quitting by educating on the benefits of medications in reducing nicotine withdrawal symptoms.

Smoking Among Individuals With Mental Illness

CASE 91-6

QUESTION 1: J.D. is a 42-year-old female presenting to clinic for follow-up of her depression management. Nine months ago, she was started on venlafaxine XR 75 mg daily. At her 3-month follow-up visit, she was stable on venlafaxine XR 150 mg daily, and her depressive symptoms had improved. She also reported that she was sleeping much better. J.D. has no other significant past medical history, and she takes no other medications. Her social history is positive for current tobacco use (one PPD for 25 years) and caffeine use (one to two Diet Coke® a day). She does not drink alcohol. During the appointment, J.D. indicates that she would like to quit smoking because her depression is better, and she knows that her overall health will improve if she quits. She also states that the last time she attempted to quit (several years ago, using the nicotine gum), she felt "down and had difficulty concentrating and couldn't sleep." She is now fearful that her depression will return if she quits.

Is smoking cessation appropriate for J.D. at this time, and what are her treatment options?

Individuals with mental illness have a higher smoking prevalence than does the general population.[85,86] Although smokers are twice as likely to have depression as do nonsmokers, the prevalence of smoking with other psychiatric diagnoses (schizophrenia, bipolar disorder, and post traumatic stress disorder) is five times higher than that for nonsmokers. Psychiatric diagnoses are associated with a higher level of nicotine dependence and lower quit rates. A growing body of evidence suggests that quitting is possible for individuals with concomitant mental illness. For these patients to achieve wellness, smoking-cessation intervention is an essential component of the overall care plan.[86]

Given that J.D. is currently willing to quit, and her depression has been stabilized for >4 months, it is appropriate for the clinician to discuss a quitting plan with J.D. and initiate therapy. The therapeutic approach should include counseling and pharmacotherapy, with ongoing monitoring of progress toward quitting and depressive symptoms.

TREATMENT SELECTION

Pharmacotherapy

Because no contraindications are present, any of the FDA-approved medications for cessation are appropriate. Although early data raised concerns regarding varenicline and changes in mood including suicidal ideation, subsequent data did not find a significant increase in neuropsychiatric adverse events in smokers prescribed varenicline.[39,57] However, the data for varenicline's neuropsychiatric effects in patients with a history of or current psychiatric disorders are less conclusive.[39,57]

Regardless of whether sustained-release bupropion, varenicline, or NRT product(s) are selected, the clinician should monitor J.D. closely to assess the incidence of depressive symptomatology. If sustained- release bupropion or varenicline is selected, J.D. should be advised to stop taking the medication and contact the clinician immediately if she experiences agitation, depressed mood, and any changes in behavior that are not typical of nicotine withdrawal, or if she experiences suicidal thoughts or behavior.

BEHAVIORAL COUNSELING

Because J.D. has indicated that she is ready to quit, the clinician should commend her for making the important decision that will positively impact her overall health. J.D. should be advised that quitting is a process, and it will be important for them to work closely together to address the physiologic as well as psychological aspects of quitting during the upcoming months.

Case 91-6, Question 2: After discussing the various treatment options with the clinician, J.D. decides that she would like to add sustained-release bupropion to her regimen because the nicotine gum by itself did not help her much last time. She also thinks that the combination of venlafaxine with bupropion might help "keep her depression more stable" while she is quitting. She confides in the clinician that her biggest fear is the ability to avoid smoking when she is stressed because of her job. She is a survey researcher and must meet client-induced deadlines. How can J.D. cope with stressful situations?

A variety of coping mechanisms can be applied to alleviate the need to smoke during stressful situations or when exposed to other triggers for smoking (Table 91-3). The clinician should encourage J.D. to think about strategies that would be effective for her in these situations, such as deep breathing or calling a supportive friend. In addition, the clinician should consider suggesting use of a short-acting NRT product (eg, nicotine gum, lozenge, inhaler, or nasal spray) as needed to alleviate situational cravings to smoke. Appropriate dosing of sustained-release bupropion should be reviewed (Table 91-4). A follow-up appointment should be scheduled for ~3 months after the quit date, and the patient should be advised to contact the clinician if she encounters any difficulties before then.

Case 91-6, Question 3: Four weeks later, J.D. calls and reports that she has a dry mouth, is having difficulty sleeping, and feels jittery and anxious. She also is currently using nicotine gum (2 mg), approximately four pieces daily. How should J.D. be managed?

As noted earlier, insomnia and dry mouth are commonly associated with sustained-release bupropion therapy, and usually lessen with continued use.[20] The nicotine gum dose is low and not likely contributing to this condition. To address insomnia, J.D. can be advised to take the second dose of the day earlier, but not <8 hours after the first dose of the day. Alternatively, the clinician could consider reducing the daily dose to 150 mg in the morning and omitting the evening dose. The 150-mg daily dose has been shown to have comparable outcomes with those of the 300-mg dose and is better tolerated.[36] The clinician also should assess J.D.'s caffeine consumption patterns and, if appropriate, suggest that she reduce her caffeine intake by 50%, and not drink caffeinated beverages after 12 noon so that her system is clear of its stimulatory properties before sleep.[19]

Extended-Use Medications for Cessation

Case 91-6, Question 4: J.D. returns to the clinician's office 3 months later and indicates that she is doing well, but had a few "slips" and smoked four times. She has not felt depressed and has been handling her stress at work through deep-breathing exercises. She uses the nicotine gum a few times a week and does not feel ready to discontinue the sustained-release bupropion. How long can she continue the therapy?

Extended-duration medication therapy appears to be safe and effective. Long-term follow-up data indicate that ~15% of long-term quitters continued nicotine gum therapy with no serious side effects.[87] The 2008 Clinical Practice Guideline states that extended use of medications might be beneficial in individuals who report persistent withdrawal symptoms during treatment, those who have relapsed shortly after medication discontinuation, or those who are interested in long-term therapy.[4] A meta-analysis of 12 trials found relapse prevention benefit with extended treatment with varenicline (with behavioral assistance) or NRT (without assistance). The relapse prevention data with bupropion alone or in combination with NRT was inconclusive, and additional study is required.[88]

Given J.D.'s current depression and because she is interested in continuing therapy, it is reasonable for the clinician to recommend the continuation of bupropion and NRT for an additional 12 weeks and reassess progress at that time. If JD does decide to discontinue her bupropion, then it should be with close monitoring by her mental health professional to assess for any rebound depressive symptoms.

Anemias

Cindy L. O'Bryant, Kate Deen Taucher, and Lisa A. Thompson

CORE PRINCIPLES		CHAPTER CASES
1	Anemias arise from multiple etiologies. A full laboratory evaluation is necessary to appropriately diagnose and determine the cause of anemia.	**Case 92-1 (Questions 1, 2)** **Case 92-2 (Question 1)** **Case 92-5 (Question 2), Figure 92-1, Tables 92-2 and 92-3**
2	Iron deficiency is the most common nutritional deficiency worldwide and is associated with symptoms of pallor, cardiovascular, respiratory, cognitive complications, and decreased quality of life.	**Case 92-1 (Question 2) Case 92-4 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
3	Oral or parenteral iron is used to treat iron deficiency anemia. The goal of therapy is an increased hemoglobin of 1–2 g/dL within 2–4 weeks of the initiation of therapy.	**Case 92-1 (Questions 1, 3–10)** **Case 92-4 (Question 2), Tables 92-6 and 92-8**
4	Distinguishing between vitamin B_{12}–deficient and folic acid–deficient megaloblastic anemia is important to minimize potentially permanent effects of these deficiencies.	**Case 92-2 (Questions 1–3)** **Case 92-3 (Question 1)** **Case 92-5 (Questions 1, 2)**
5	Patients with sickle cell disease should receive appropriate preventive care, including infection prophylaxis with penicillin and routine immunizations.	**Case 92-6 (Questions 1, 2)**
6	Acute sickle cell crises are an urgent situation and should be managed with pain control, transfusions, oxygen, or antibiotic therapy as appropriate.	**Case 92-7 (Questions 1–3)**
7	The goals of treatment for sickle cell anemia are symptom control and management of disease complications. Current treatments have shown a reduction in vaso-occlusive events, decreased hospitalizations, or improved hemoglobin response.	**Case 92-7 (Question 4–6)**

CORE PRINCIPLES		CHAPTER CASES
8	Anemia of inflammation is associated with the upregulation of inflammatory cytokines that results in shortened red blood cell survival and decreased production. Treatment focuses on the underlying disease and the use of erythropoietin (EPO).	**Case 92-8 (Question 1)**
9	Response to EPO depends on the dose and underlying cause of anemia. Lack of response to treatment with erythropoiesis-stimulating agents (ESAs) is commonly associated with functional or absolute iron deficiency.	**Case 92-8 (Question 1)**

INTRODUCTION

Anemia is a reduction in red blood cell (RBC) mass. It is often described as a decrease in the number of RBCs per microliter (μL) or as a decrease in the hemoglobin (Hgb) concentration in the blood to a level below the normal physiologic requirement for adequate tissue oxygenation. The term *anemia* is not a diagnosis, but rather an objective sign of a disease. Diagnostic terminology for anemia requires the inclusion of the pathogenesis (eg, microcytic anemia secondary to iron deficiency) in order to implement the appropriate specific therapy to correct the anemia.

Pathophysiology

Anemia is a symptom of many pathologic conditions. It is associated with nutritional deficiencies, acute and chronic diseases, and may be

drug-induced. Anemia is also caused by decreased RBC production, increased RBC destruction, or increased RBC loss. When anemia is caused by decreased RBC production, it may be the result of disturbances in stem cell proliferation or differentiation. Anemias caused by increased RBC destruction can be secondary to hemolysis, whereas increased RBC loss may be caused by acute or chronic bleeding. Anemias associated with acute blood loss, those that are iron-related, and those caused by inflammation constitute most anemias.[1] Classifications of anemias according to pathophysiologic and morphologic characteristics are shown in **Table 92-1**.

Table 92-1
Classifications of Anemia

Pathophysiologic (Classifies Anemias Based on Pathophysiologic Presentation)
Blood Loss
Acute: trauma, ulcer, hemorrhoids
Chronic: ulcer, vaginal bleeding, aspirin ingestion
Inadequate Red Blood Cell Production
Nutritional deficiency: vitamin B_{12}, folic acid, iron
Erythroblast deficiency: bone marrow failure (aplastic anemia, irradiation, chemotherapy, folic acid antagonists) or bone marrow infiltration (leukemia, lymphoma, myeloma, metastatic solid tumors, myelofibrosis)
Endocrine deficiency: pituitary, adrenal, thyroid, testicular
Chronic disease: renal, liver, infection, granulomatous, collagen vascular
Excessive Red Blood Cell Destruction
Intrinsic factors: hereditary (G6PD), abnormal hemoglobin synthesis
Extrinsic factors: autoimmune reactions, drug reactions, infection (endotoxin)
Morphologic (Classifies Anemias by Red Blood Cell Size [Microcytic, Normocytic, Macrocytic] and Hemoglobin Content [Hypochromic, Normochromic, Hyperchromic])
Macrocytic
Defective maturation with decreased production

Pathophysiologic (Classifies Anemias Based on Pathophysiologic Presentation)
Blood Loss
Megaloblastic: pernicious (vitamin B_{12} deficiency), folic acid deficiency
Normochromic, Normocytic
Recent blood loss
Hemolysis
Chronic disease
Renal failure
Autoimmune
Endocrine
Microcytic, Hyperchromic
Iron deficiency
Genetic abnormalities: sickle cell, thalassemia

G6PD, glucose-6-phosphate dehydrogenase.

Normally, RBC mass is maintained by feedback mechanisms that regulate levels of erythropoietin (EPO), a hormone that stimulates the proliferation and differentiation of erythroid precursors in the bone marrow. Two types of erythroid precursors reside in the bone marrow: the burst forming unit–erythrocyte cell (BFUe) and colony forming unit–erythrocyte cell (CFUe). The BFUe is the earliest progenitor, which eventually develops into a CFUe. The BFUe is moderately sensitive to EPO and is under the influence of other cytokines (eg, interleukin [IL] 3, granulocyte-macrophage colony-stimulating factor [GM-CSF]). In contrast, the CFUe is highly sensitive to EPO and differentiates into erythroblasts and reticulocytes. The kidneys produce 90% of EPO; liver synthesis accounts for the remainder. Reduced oxygen-carrying capacity is sensed by renal peritubular cells, which stimulate the release of EPO into the bloodstream. Patients with chronic anemia may have a blunted and inadequate EPO response for the degree of anemia present.

Detection

SIGNS AND SYMPTOMS

Signs and symptoms of anemia vary with the degree of RBC reduction as well as with the time to development. The decreased oxygen-carrying capacity of the reduced RBC mass results in tissue hypoxia followed by decreased perfusion to nonvital tissues (eg, skin, mucous membranes, extremities) in order to sustain tissue perfusion of vital organs (eg, brain, heart, kidneys). Slowly developing anemias can be asymptomatic initially or include symptoms such as slight exertional dyspnea, increased angina, fatigue, or malaise.[1,2]

In severe anemia (Hgb >8 g/dL), heart rate and stroke volume often increase in an attempt to improve oxygen delivery to tissues. These changes in heart rate and stroke volume can result in systolic murmurs, angina pectoris, high-output heart failure, pulmonary congestion, ascites, and edema. Thus, anemia is generally not well tolerated in patients with cardiac disease. Skin and mucous membrane pallor, jaundice, smooth or beefy tongue, cheilosis, and spoon-shaped nails (koilonychia) also may be associated with severe anemia of different etiologies.

HISTORY

A thorough history, including a timeline of onset of symptoms and current clinical status, and physical examination are essential because of the complexity of the pathologic conditions associated with anemia. When evaluating a patient for the diagnosis of anemia, histories should include (a) past and current Hgb or hematocrit (Hct) values; (b) transfusion history; (c) family history, because longstanding anemias can indicate hereditary disorders; (d) occupational, environmental, and social histories; and (e) medication history to eliminate drug reactions or interactions as the cause of the anemia.

PHYSICAL EXAMINATION

Pallor is most easily observed in the conjunctiva, mucous membranes, nail beds, and palmar creases of the hand. In addition, postural hypotension and tachycardia can be seen when hypovolemia (acute blood loss) is the primary cause of anemia. Patients with vitamin B_{12} deficiency may exhibit neurologic findings consistent with nerve fiber demyelination, which may include changes in deep tendon reflexes, ataxia, and loss of vibration and position sense. Patients with anemia from hemolysis may be slightly jaundiced from bilirubin release. Manifestations of hemorrhage can include petechiae, ecchymoses, hematomas, epistaxis, bleeding gums, and blood in the urine or the stool.

LABORATORY EVALUATION

Although anemia may be suspected from the history and physical examination, a full laboratory evaluation is necessary to confirm the diagnosis, establish severity, and determine the cause. A list of the routine laboratory evaluations used in the workup for anemia is found in **Table 92-2**. The cornerstone of this evaluation is the complete blood count (CBC). Other evaluations assessing nutritional deficiencies, including iron studies, vitamin B_{12}, and folate as well as EPO levels may also provide insight into the cause of anemia as shown in **Table 92-3**. Males have higher normal Hgb and Hct values than do females. The Hgb and Hct are increased in individuals living at altitudes >4000 feet in response to the diminished oxygen content of the atmosphere and blood.

Table 92-2

Routine Laboratory Evaluation for Anemia Workup

CBC: Hgb, Hct, RBC count, RBC indices (MCV, MCH, MCHC), WBC count (and differential)
Platelet count
RBC morphology
Reticulocyte count
Bilirubin and LDH
Serum iron, TIBC, serum ferritin, transferrin saturation
Peripheral blood smear examination

Stool examination for occult blood	
Bone marrow aspiration and biopsy[a]	

CBC, complete blood count; Hct, hematocrit; Hgb, hemoglobin; LDH, lactate dehydrogenase; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell; TIBC, total iron-binding capacity; WBC, white blood cell.

[a]Performed in patients with abnormal peripheral blood smears.

Table 92-3

Supplemental Hematology Values

	Pediatric	Adult	
Laboratory Test	**1–15 years**	**Male**	**Female**
Erythropoietin (milliunits/mL)	4–26	4–26	4–26
Reticulocyte count (%)	0.5–1.5	0.5–1.5	0.5–1.5
TIBC (mg/dL)	250–400	250–400	250–400
Fe (mg/dL)	50–120	50–160	40–150
Fe/TIBC (%)	20–30	20–40	16–38
Ferritin (ng/mL)	7–140	15–200	12–150
Folate (ng/mL)	7–25	7–25	7–25
RBC folate (ng/mL)	—	140–960	140–960
Vitamin B_{12} (pg/mL)	>200	>200	>200

Fe, iron; RBC, red blood cell; TIBC, total iron-binding capacity.

The morphologic appearance of the RBC found in RBC indices included as part of the CBC, including mean corpuscular volume (MCV), mean cell Hgb (MCH), and mean cell Hgb concentration (MCHC), provide useful information about the nature of the anemia. Note: corpuscular and cell may be used interchangeably when referring to MCV, MCH, and so on. Microscopic evaluation of the peripheral blood smear can detect the presence of macrocytic (large) RBCs, which are associated with vitamin B_{12} or folic acid deficiency, or microcytic (small) RBCs, typically associated with iron deficiency

anemia. Acute blood loss generally is associated with normocytic cells.

The history and physical examination and laboratory evaluation typically provide sufficient information to distinguish among the most common forms of anemia (**Fig. 92-1**). If not identified after routine evaluation, problems such as autoimmune disease, collagen vascular disease, chronic infection, or endocrine disorders may be causing the anemia. When uncertainty exists or an abnormal peripheral blood smear is noted, a bone marrow aspiration with biopsy is indicated.

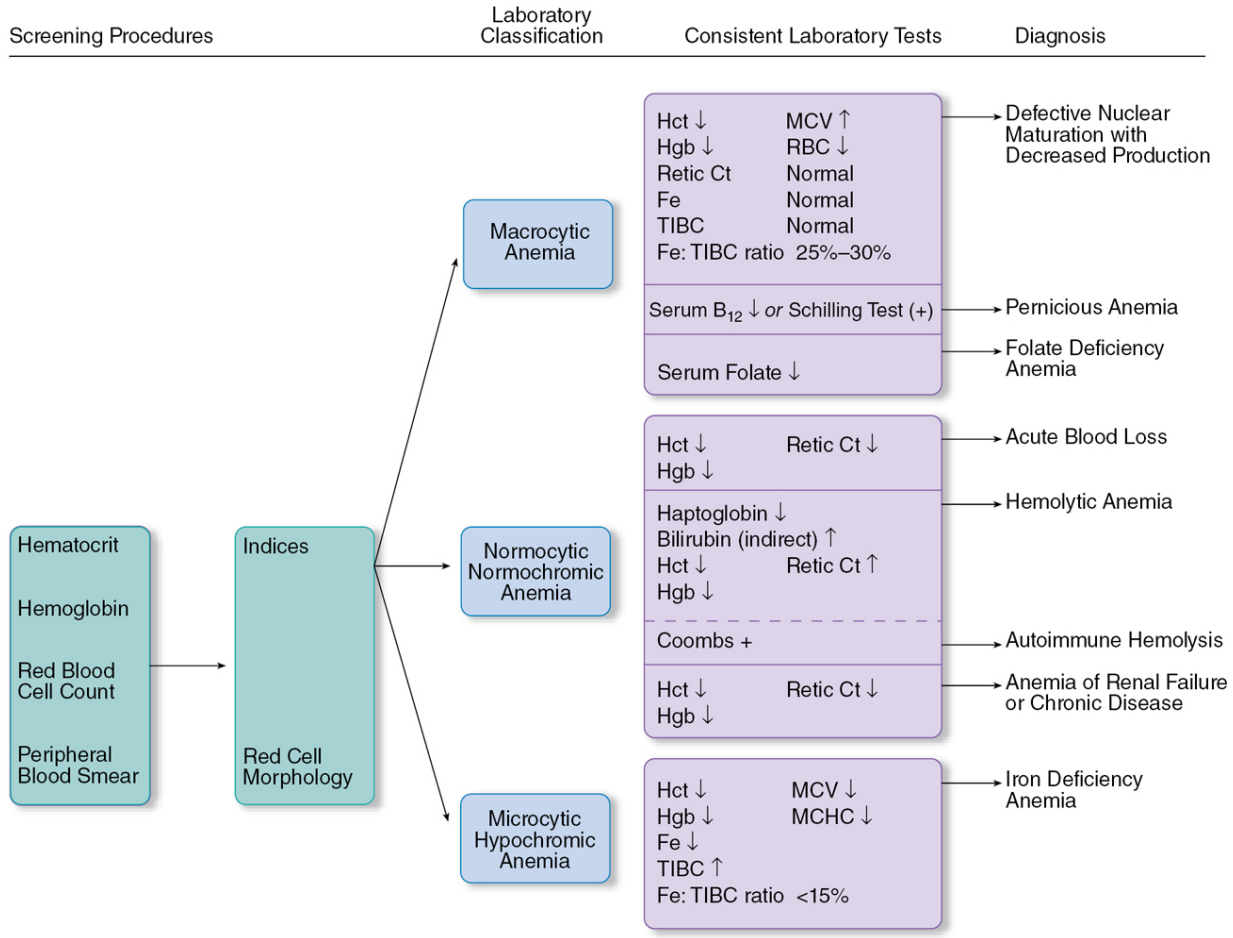

Figure 92-1 Laboratory diagnosis of anemia.

There are many causes of anemia. This chapter is limited to the most common anemias and their medication management. Hemolytic anemias will not be discussed. Before proceeding, the

reader should review the basic hematologic laboratory tests used to evaluate and monitor anemia (see Chapter 2, Interpretation of Clinical Laboratory Tests).

IRON DEFICIENCY ANEMIA

Iron deficiency occurs when iron intake and stores are unable to meet body requirements, depleting total-body iron.[3] The body contains ~3 to 4 g of iron, of which 2.5 g is found in RBCs.[4,5] Only a small fraction of iron is found in plasma and most is bound to transferrin, a transport protein.[4]

Despite the continual turnover of RBCs, iron stores are well preserved because >95% of iron is recovered and reused in new erythrocytes.[6] Males and nonmenstruating females lose about 1 to 2 mg/day of iron from minor bleeding, urine, sweat, and the sloughing of ferritin-containing intestinal mucosal cells.[4] Menstruating females lose approximately an additional 16 mg of iron per period.[6] Pregnancy and lactation are other common sources of iron loss (see Chapter 49, Obstetric Drug Therapy).

Individuals with normal iron stores absorb roughly 10% of ingested dietary iron. The average American diet contains 5 to 15 mg of elemental iron and 1 to 5 mg of heme iron, resulting in 1 to 2 mg of absorbed iron from the intestines. The average daily iron requirement for various populations is shown in **Table 92-4**.

Table 92-4
Dietary Reference Intake for Iron

	mg/day
Healthy, nonmenstruating adults	8
Menstruating females	18
Pregnant females	27
Lactating females	9

	mg/day
Vegetarians	16[a]
Preterm infants	2–4
Term infants (birth to 6 months)	0.27
Term infants (7–12 months)	11
Toddlers (1–3 years)	7

[a]Twofold higher than those not consuming a vegetarian diet.

Sources: National Academy of Sciences, Institute of Medicine, Food and Nutrition Board. *Dietary Reference Intakes for Vitamin A, Vitamin K, Arsenic, Boron, Chromium, Copper, Iodine, Iron, Manganese, Molybdenum, Nickel, Silicon, Vanadium, and Zinc*. National Academies Press; 2001; Baker RD, Greer FR; Committee on Nutrition American Academy of Pediatrics. Diagnosis and prevention of iron deficiency and iron-deficiency anemia in infants and young children (0–3 years of age). *Pediatrics*. 2010;126:1040–1050.

Iron is absorbed from the duodenum and upper jejunum by an active transport mechanism. Dietary iron exists primarily in the ferric state and is converted to the more readily absorbed ferrous form in the acidic environment of the stomach. The ferrous form binds to transferrin for transport to the bone marrow, where it is incorporated into the Hgb of mature erythrocytes.

Gastrointestinal (GI) absorption of iron is increased in iron deficiency states or when erythropoiesis occurs at a more rapid rate.[3] Animal sources of iron (heme iron) are better absorbed than plant sources (nonheme iron). Iron deficiency accounts for half the cases of anemia worldwide. Although iron deficiency anemia has many causes, including altered iron absorption (**Table 92-5**), blood loss is one of the more common.

Table 92-5
Iron Deficiency Anemia Causes

Blood Loss
Menstruation, gastrointestinal (eg, peptic ulcer), trauma, blood donation, hemorrhoids, ingestion of GI irritants, menstruation, multiple pregnancies
Decreased Absorption

Blood Loss
Medications, gastrectomy, bariatric surgery, celiac, regional enteritis
Increased Requirement
Infancy, pregnant/lactating females, adolescence
Impaired Utilization
Hereditary, iron use
Environmental
Insufficient intake, diet (eg, vegetarian)

Source: Baker RD, Greer FR; Committee on Nutrition American Academy of Pediatrics. Diagnosis and prevention of iron deficiency and iron-deficiency anemia in infants and young children (0–3 years of age). *Pediatrics.* 2010;126:1040–1050.

Dietary reference intakes (DRIs) for iron are listed in **Table 92-4**.[7,8] The increased amounts of iron required by pregnant or lactating females are difficult to obtain through diet alone; oral iron supplementation generally is necessary. Although maternal iron usually provides term infants with sufficient stored iron for the first 6 months, infants ages 6 months to 3 years' experience rapid growth and a threefold increase in blood volume, which can increase the risk of iron deficiency. Premature infants have reduced iron stores and thus require replacement therapy.

Predisposing Factors

CASE 92-1

Question 1: H.P. is a 31-year-old female seen in the clinic for weakness, dizziness, and epigastric pain. She has a 5-year history of peptic ulcer disease, a 10-year history of heavy menstrual bleeding, and a 15-year history of chronic headaches. She has two children who are 1 and 3 years old. H.P. is currently taking minocycline 100 mg twice daily (bid) for acne, ibuprofen 400 mg as needed for headaches, and esomeprazole 40 mg daily. Her review of systems is positive for decreased exercise tolerance. Physical examination reveals a pale, lethargic, White female appearing older than her stated age. Her vital signs are within normal limits; her heart rate is regular at 100 beats/minute. Her examination is notable for pale nail beds and splenomegaly.

Significant laboratory results include the following:

Hgb, 8 g/dL
Hct, 26%
Platelet count, 500,000/μL
Reticulocyte count, 0.2%
MCV, 75 femtoliters (fL)
MCH, 23 pg/cell
MCHC, 300 g/L
Serum iron, 40 μg/dL
Serum ferritin, 9 ng/mL
Total iron-binding capacity (TIBC), 450 g/dL
4+ stool guaiac (normal, negative)

Iron deficiency is determined to be the cause of H.P.'s anemia. An upper GI series with a small bowel follow-through is planned to evaluate her persistent epigastric pain.

What factors predispose H.P. to iron deficiency anemia?

Several factors predispose H.P. to iron deficiency anemia. Her history of heavy menstrual bleeding and the 4+ stool guaiac indicate menstrual and GI sources of blood loss. The GI blood loss may be secondary to H.P.'s chronic use of nonsteroidal anti-inflammatory drugs, recurrent peptic ulcer disease, or both.

Many menstruating patients have a borderline iron deficiency that becomes more evident with pregnancy's increased iron requirements[3]; H.P. has given birth to two children in recent years. Additionally, dietary iron absorption may be compromised by her use of proton-pump inhibitors and minocycline (see Case 92-1, Question 6).

Signs, Symptoms, and Laboratory Tests

Case 92-1, Question 2: What subjective or objective signs, symptoms, and laboratory tests are typical of iron deficiency in H.P.?

H.P.'s constitutional symptoms of weakness and dizziness could be a result of her severe anemia. Generally, until the anemia is severe, such symptoms occur with equal frequency in the

nonanemic population. The most important signs and symptoms of iron deficiency anemia are related to the cardiovascular system and reflect the imbalance between ongoing demands for oxygen against diminishing oxygen supply.

H.P.'s increased heart rate, decreased exercise tolerance, and pale appearance are consistent with the cardiovascular response seen in iron deficiency anemia. In patients who are not yet symptomatic, iron stores can be assessed by measuring ferritin. Although primarily an intracellular protein, serum concentrations of ferritin correlate closely with iron stores with only a few exceptions.[9] Ferritin is an acute-phase reactant and is generally higher in patients with inflammatory disorders, infection, malignancy, liver disease, and chronic renal failure.[9] An increased TIBC also can indicate iron depletion but is less sensitive than serum ferritin. If the TIBC is low or normal, rather than high, in association with low serum ferritin, other causes of anemia should be considered and evaluated with additional labs and bone marrow examination.

H.P.'s low serum iron, low serum ferritin, and elevated TIBC are typical of the laboratory findings associated with iron deficiency anemia. Serum transferrin receptor levels, which reflect the amount of RBC precursors available for active proliferation, are increased in iron deficiency. After stored iron is depleted, heme and Hgb synthesis is decreased. In severe iron deficiency, the RBCs become hypochromic (low MCHC) and microcytic (low MCV),[5] as seen in H.P.

The reticulocyte count provides an estimate of effective RBC production and is usually normal or low in iron deficiency anemia, consistent with H.P.'s results.

In the workup of a microcytic, hypochromic anemia, the stool should be examined for occult blood. H.P. has a 4+ stool guaiac, suggesting GI blood loss. Further diagnostic evaluation is necessary to determine the underlying problem.

Iron Therapy

ORAL IRON DOSING

Case 92-1, Question 3: How should H.P.'s iron deficiency be managed? What dose of iron should be given to treat H.P.'s iron deficiency anemia?

The primary treatment should be directed toward control of the underlying causes of anemia: GI blood loss, multiple childbirths, heavy menstrual flow, decreased dietary iron absorption, and perhaps, an inadequate diet. The cause of her GI blood loss should be corrected, her dietary intake should be analyzed and modified, and supplemental iron should be prescribed to replenish her stores and correct the anemia.

The usual adult dose of iron is 100 to 200 mg elemental iron, frequently administered as ferrous sulfate 325 mg (one tablet) taken three times daily between meals. Because of saturable absorption of iron in the intestines, repletion with lower doses or administration on alternating days has been shown to be effective and may minimize side effects and improve compliance.[3,10]

PRODUCT SELECTION

Case 92-1, Question 4: What are the differences between iron products? Which is the product of choice?

The ferrous form of iron is absorbed three times more readily than the ferric form. Although ferrous sulfate, ferrous gluconate, and ferrous fumarate are absorbed almost equally, each contains a different amount of elemental iron that is available for absorption.[11] Carbonyl iron, another iron product, must be solubilized by gastric acid to be absorbed, which may limit use. **Table 92-6** compares the iron content of several oral iron salts to assist in making appropriate treatment choices for patients.

Table 92-6
Comparisons of Oral Iron Preparations

Preparation	Dose (mg)	Fe^{2+} Content (mg)	Fe (%)
Ferrous sulfate	325	65	20
Ferrous fumarate	325	106	33
Ferrous gluconate	324	38	12
Ferrous sulfate, exsiccated (dried)	160	50	32

Note: This is a representative list of examples of oral iron preparations that may be used.

Source: Adapted with permission from Facts & Comparisons eAnswers. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/doc/retrieve/docid/fc_dfc/5546092?searchUrl=%2Flco%2Faction%2Fsearch%3Fq%3Diron%26t%3Dname%26va%3Diron%26nq%3Dtrue.

Product formulation

Product formulation is of considerable importance in product selection. Enteric-coated and sustained release (SR) preparations are purported to increase GI tolerance or decrease side effects; however, these products are frequently more expensive than immediate release formulations. Some of these products can be given once daily, which may enhance adherence. Unfortunately, enteric-coated products transport iron past the duodenum and proximal jejunum, reducing absorption.[5] As poor absorption and poor hematologic responses might occur with SR formulations, these are not ideal for initial treatment.

Adjuvants are incorporated into some iron preparations in an attempt to enhance absorption or mitigate side effects. An acidic environment is needed for absorption in the duodenum and upper jejunum. Ascorbic acid (vitamin C, up to 1 g) is able to increase iron absorption by ~7%; however, this may increase GI side effects[10] and smaller doses do not significantly improve iron absorption.[12] To decrease constipation, stool softeners may be added,[5] although not always at adequate doses. H.P. should take the least expensive iron preparation containing ferrous sulfate, gluconate, or fumarate.

GOALS OF THERAPY

CASE 92-1, QUESTION 5: What are the goals of iron therapy? How long H.P. should be treated? How should H.P. be monitored?

The goals of iron therapy are to normalize Hgb and Hct and to replete iron stores. If the iron dose is adequate, the reticulocyte count will begin to increase by the 3rd to 4th day and peak by the 7th to 10th day of therapy. By the end of the second week of iron therapy, the reticulocyte count will normalize. Hgb response is a convenient index to monitor in outpatients. Hematologic response is usually seen in 2 to 3 weeks with a 1 to 2 g/dL increase in Hgb and a 6% increase in the hematocrit. H.P.'s anemia can be expected to resolve in 1 to 2 months; however, iron therapy should be continued for 3 to 6 months after Hgb normalizes to replete iron stores.[9]

PATIENT INFORMATION

CASE 92-1, QUESTION 6: What information should be provided to H.P. when dispensing oral iron? What can be done if she experiences intolerable GI symptoms (eg, nausea, epigastric pain)?

Iron should be dispensed in a child-resistant container, and H.P. should be counseled to store it in a place inaccessible to her young children. Accidental ingestion of oral iron can cause serious consequences in small children[13] (see Chapter 5, Managing Drug Overdoses and Poisonings). H.P. should be told that oral iron therapy produces dark stools. She should try to take her iron on an empty stomach because food, especially foods rich in calcium, phytates or tannins, decreases absorption.[10]

GI side effects occur in 5% to 20% of patients and include nausea, epigastric pain, constipation, abdominal cramps, and diarrhea. Constipation does not appear to be dose-related, but other side effects (eg, nausea and epigastric pain) occur more frequently with higher doses because the quantity of soluble elemental iron in

contact with the stomach and duodenum increases.[5] To minimize GI intolerance, oral iron can be initiated with a single tablet of ferrous sulfate 325 mg/day and increased by increments of one tablet per day every 2 to 3 days until the full therapeutic dose of 325 mg three times daily can be administered.

H.P. should be educated about potential drug interactions that can occur with iron therapy. She is taking a proton-pump inhibitor, which like other acid-suppressing medications, may inhibit serum iron absorption by increasing the stomach pH and decreasing iron solubility. H.P. is also taking minocycline; because both iron and minocycline absorption are decreased when administered concomitantly; these should be taken at least 2 hours apart. **Table 92-7** provides additional drug interactions to be considered.

Table 92-7
Select Drug Interactions With Iron Salts

Precipitant Drug	Object Drug		Description
Antacids	Iron salts	↓	GI absorption of iron may be reduced; separate administration times.
Ascorbic acid	Iron salts	↑	Ascorbic acid at doses ≥200 mg have been shown to enhance the absorption of iron ≥30%.
Calcium salts	Iron salts	↓	GI absorption of iron may be reduced. When possible, separate administration times.
Chloramphenicol	Iron salts	↑	Serum iron levels may be increased.
Digestive enzymes	Iron salts	↓	The serum iron response to oral iron may be decreased by concomitant pancreatic extracts.
H_2 antagonists	Iron salts	↓	GI absorption of iron may be reduced.
Proton-pump inhibitors	Iron salts	↓	GI absorption of iron may be reduced.
Trientine	Iron salts	↓	The two agents inhibit the absorption of each other. If iron is needed, administer the agents at least 2 hours apart.
Iron salts	Trientine		
Iron salts	Oral bisphosphonates	↓	Reduced bisphosphonate absorption; avoid administration within 2 hours before or after.
Iron salts	Captopril	↓	Concomitant use within 2 hours may promote the formation of inactive captopril disulfide dimer.
Iron salts	Cephalosporins (eg, cefdinir)	↓	Iron supplements and foods fortified with iron may reduce the absorption of cefdinir 80% and 30%, respectively. If iron supplements are needed during cefdinir therapy, cefdinir should be taken 2 hours before or after the supplement. Iron-fortified infant formula (elemental iron 2.2 mg per 6 oz) has no effect on cefdinir absorption.

Iron salts	Fluoroquinolones (eg, ciprofloxacin)	↓	GI absorption of fluoroquinolones may be decreased because of the formation of iron–quinolone complex. Avoid coadministration of these drugs. (See individual fluoroquinolone monographs for administration recommendations.)
Iron salts	Levodopa	↓	Levodopa appears to form chelates with iron salts, decreasing levodopa absorption and serum levels.
Iron salts	Levothyroxine	↓	The efficacy of levothyroxine may be decreased, resulting in hypothyroidism. Avoid coadministration.
Iron salts	Methyldopa	↓	Extent of methyldopa absorption may be decreased, possibly resulting in decreased efficacy.
Iron salts	Mycophenolate mofetil	↓	Absorption of mycophenolate mofetil may be decreased. Avoid simultaneous administration.
Iron salts	Penicillamine	↓	Marked reduction in GI absorption of penicillamine may occur, possibly because of chelation.
Iron salts	Tetracyclines	↓	Concomitant use within 2 hours may decrease absorption and serum levels of tetracyclines. Absorption of iron salts also may be decreased.
Tetracyclines	Iron salts		
Iron salts	Thyroid hormones	↓	Absorption of thyroid hormones may be decreased. Avoid coadministration.

↑, object drug increased; ↓, object drug decreased.

PARENTERAL IRON THERAPY

Indications

Case 92-1, Question 7: When would parenteral iron therapy be indicated for H.P.?

Causes of oral therapy failure can include nonadherence, misdiagnosis, inflammatory conditions, malabsorption (eg, gastric bypass, celiac disease), the need for rapid iron repletion, and continuing blood loss equal to or greater than the rate of RBC production.[4,9] Other indications for parenteral iron administration include intolerance to oral therapy, required antacid therapy, or significant blood loss in patients refusing transfusion. In H.P.'s case intolerance, continued blood loss, long-term antacid therapy, and malabsorption may be potential indications for parenteral iron.

Preferred route

Case 92-1, Question 8: What is the preferred formulation of parenteral iron?

Iron can be given parenterally as ferric gluconate, iron dextran, iron sucrose, ferric carboxymaltose, and ferumoxytol (**Table 92-8**). Comparison between agents reveals similar efficacy with differences in cost analysis from diverse administration schedules.[14] Iron dextran and ferric carboxymaltose are U.S. Food and Drug Administration (FDA) approved for the treatment of iron deficiency when oral supplementation is impossible or ineffective. All parenteral iron products can be administered undiluted slowly as an intravenous (IV) push or diluted and administered by infusion. Iron dextran is the only product that may be given intramuscularly (IM), which may be preferred in patients with limited IV access. Although data are limited, infusion of the total dose (total estimated iron deficit) of iron dextran is given in clinical practice and has proved to be effective and convenient.[15] The total dose method of administration can be associated with a higher prevalence of fever, malaise, flushing, and myalgias. Because of the potential for anaphylaxis with iron dextran, a 25-mg IM or IV test dose should be given. Test doses prior to subsequent infusions should be considered but are not required.

Table 92-8
Comparison of Parenteral Iron Preparations

Preparation	Dosage Form	Usual Dose	Maximum Dose
Ferric carboxymaltose	Solution for injection: 50 mg/mL (elemental iron)	Weight ≥50 kg: 750 mg per dose Weight <50 kg: 15 mg/kg per dose Repeat dose ≥7 days	1500 mg (cumulative per treatment course)
Ferumoxytol	Solution for injection: 30 mg/mL (elemental iron)	510 mg per dose; repeat once 3–8 days later Off-label regimen: 1020 mg single dose	N/A
Iron dextran (low molecular weight)	Solution for injection: 50 mg/mL (elemental iron)	Test dose: 25 mg; followed by remainder of dose (typically not >975 mg)	100 mg/day per prescribing information; 1000 mg per infusion more typical of current practice[8]
Iron sucrose	Solution for injection: 20 mg/mL (elemental iron)	**HD:** 100 mg during consecutive HD sessions for 10 doses **CKD, nondialysis:** 200 mg on five different occasions over 14 days; 500 mg once on days 1 and 14 **CKD, PD:** 300 mg IV days 1 and 14, then 400 mg on day 28	N/A
Sodium ferric gluconate complex	Solution for injection: 12.5 mg/mL (elemental iron)	125 mg per dose (usually repeated to cumulative dose of 1000 mg)	N/A

CKD, chronic kidney disease; HD, hemodialysis; PD, peritoneal dialysis.

Source: Data from Facts & Comparisons eAnswers. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/home

Ferric gluconate, iron sucrose, and ferumoxytol are FDA-approved parenteral iron formulations used to treat iron deficiency anemia in patients with chronic kidney disease undergoing chronic hemodialysis. Ferric carboxymaltose is indicated for the treatment of iron deficiency anemia in nondialysis-dependent chronic kidney disease. A test dose is not required for these agents because of the lower incidence of serious anaphylactoid reactions. Iron requirements may exceed 1 to 2 g, requiring multiple doses to achieve the intended dose of iron.

Dosage calculation

Case 92-1, Question 9: What is the total dose of iron dextran for IV infusion that would be needed to achieve a normal Hgb value for H.P. and to replenish her iron stores? How quickly should she respond?

The total dose of iron dextran to be administered can be determined using the following equation.

$$\text{Iron (mg)} = \text{Weight (pounds)} \times 0.3 \{100 - [100(\text{Hgb})/14.8]\} \quad \textbf{(Eq. 92-1)}$$

Where Hgb is the patient's measured Hgb (g/dL).

The equation uses the person's weight (in pounds) and assumes that an Hgb of 14.8 g/dL is 100% of normal. Children weighing <30 pounds (13.60 kg) should be given 80% of the calculated dose because the normal mean Hgb in this population is lower.

For patients with anemia resulting from blood loss (eg, hemorrhagic diathesis) or patients receiving chronic dialysis, the iron requirement is based on the estimate of iron contained in the blood lost. In this case, the following equation should be used:

$$\text{Iron (mg)} = \text{Blood loss (mL)} \times \text{Hct (the patient's measured Hct expressed as a decimal fraction)} \quad \textbf{(Eq. 92-2)}$$

This formula assumes that 1 mL of normochromic blood contains 1 mg of iron.

Because the rate of iron incorporation into Hgb does not exceed that achieved by oral iron therapy, the hematologic response time is similar to that of oral iron therapy.

Side effects

Case 92-1, Question 10: What side effects can be expected from parenteral iron therapy?

Overall, serious adverse reactions reported with parenteral iron administration are rare.[16] Anaphylactoid reactions occur in <1% of patients treated with parenteral iron therapy and are more commonly associated with iron dextran and ferumoxytol than with ferric gluconate and iron sucrose.[16,17] Other side effects seen with parenteral iron agents include chest pain, headache, hypotension, nausea and vomiting, cramps, and diarrhea.

MEGALOBLASTIC ANEMIAS

Megaloblastic anemia is a common disorder that can have several causes, such as vitamin B_{12} deficiency, folate deficiency, or by related conditions that cause impaired DNA synthesis.[18,19]

Megaloblastosis results from impaired DNA synthesis in replicating cells, which is signaled by a large immature nucleus.[18] RNA and protein synthesis remain unaffected, and the cytoplasm matures normally. Megaloblastic changes can be observed microscopically in RBC and in proliferating cells (eg, in the cervix, skin, GI tract). The extent of RBC macrocytosis is reported as MCV, calculated as shown below.

$$\text{MCV (fL)} = [\text{Hct (percent)} \times 10]/[\text{RBC count } (10^6/\mu\text{L})]$$

Although the clinical effects of vitamin B_{12} and folic acid deficiencies can differ in various organ systems, they are similar in their effects on the hematopoietic system. Typically, macrocytic anemia develops slowly and is characterized by large, oval, well-hemoglobinized RBCs; anisocytosis; and nuclear remnants. The reticulocyte count is low, and the bilirubin level is elevated. If biopsied, the bone marrow is markedly hypercellular. Nuclear immaturity is present, but the megaloblasts have normal maturation of the cytoplasm. Iron stores in the marrow are increased as a result of the intramedullary hemolysis. Symptoms include fatigue; exaggeration of preexisting cardiovascular or pulmonary problems; a sore, pale, smooth tongue; diarrhea or constipation; and anorexia.[20,21]

(Eq. 92-3)

Vitamin B_{12} Deficiency Anemia

VITAMIN B_{12} METABOLISM

Deficiency and poor utilization of vitamin B_{12} are two mechanisms for the development of megaloblastic anemia.[21] Vitamin B_{12} (cobalamin) is naturally synthesized by microorganisms, but humans must obtain vitamin B_{12} in their diet. Animal protein and fortified foods provide the majority of dietary vitamin B_{12}.[22] The typical Western diet contains 3.5 to 5 µg/day of vitamin B_{12}, an amount sufficient to replace up to 1 µg lost daily through urine, sweat, and other body secretions.

In the stomach, vitamin B_{12} is released from protein complexes and bound to intrinsic factor, which protects it from degradation by GI microorganisms. Intrinsic factor is essential for the absorption of vitamin B_{12}. Specific mucosal receptors in the distal small ileum allow for attachment of the intrinsic factor–vitamin B_{12} complex, which is then transferred to the ileal cell and, finally, to portal vein blood.

After vitamin B_{12} is absorbed, it is bound to specific β-globulin transport proteins, transcobalamins I, II, and III. Transcobalamin II is responsible for transporting absorbed vitamin B_{12} through cell

membranes and delivering it to the liver and other organs. In the liver, vitamin B_{12} is converted to coenzyme B_{12}, which is essential for hematopoiesis, maintenance of myelin throughout the entire nervous system, and production of epithelial cells.

Total body stores of vitamin B_{12} range from 2000 to 3000 µg, ~50% of which is stored in the liver. Because body stores are extensive, 5 to 10 years are required before symptoms of vitamin B_{12} deficiency develop.[20]

PATHOGENESIS AND EVALUATION OF VITAMIN B_{12} DEFICIENCY

Vitamin B_{12} deficiency can result from decreased supply (reduced intake, absorption, transport, or utilization) or increased requirement (greater metabolic consumption, destruction, and excretion). Other causes of vitamin B_{12} deficiency include inadequate proteolytic degradation of vitamin B_{12} from protein or congenital intrinsic factor deficiency. In addition, the gastric mucosa may be unable to produce intrinsic factor under conditions such as partial gastrectomy, autoimmune destruction (eg, Addisonian or juvenile pernicious anemia), or destruction of the gastric mucosa from caustic agents.

Pernicious anemia can result in vitamin B_{12} deficiency.[23,24] It can be caused by chronic atrophic gastritis accompanied by reduced intrinsic factor and hydrochloric acid secretion or acquired as a result of gastrectomy, pancreatic disease, or malnutrition. Pernicious anemia occurs commonly in patients with thyrotoxicosis, autoimmune thyroiditis, vitiligo, rheumatoid arthritis, or gastric cancer. Intrinsic factor and parietal cell autoantibodies may be observed in the serum of patients with pernicious anemia.

The onset of pernicious anemia is insidious. Patients generally do not feel well for months and often report at least two of the following symptoms: weakness, sore tongue, and symmetric numbness or tingling in the extremities. The neurologic symptoms of vitamin B_{12} deficiency are associated with a defect in myelin synthesis and often

are described as peripheral neuropathy or nonspecific symptoms (eg, tinnitus, neuritis, vertigo, headaches).

LABORATORY EVALUATION

In general, the serum vitamin B_{12} level reliably reflects vitamin B_{12} tissue stores. Falsely low vitamin B_{12} concentrations may be observed in patients with folic acid deficiency, transcobalamin I deficiency, multiple myeloma, or pregnancy.[20] Falsely normal levels may be observed in patients with myeloproliferative, liver, or renal disease. Measuring serum methylmalonic acid and homocysteine levels may also differentiate between folate and vitamin B_{12} deficiency. Once vitamin B_{12} therapy has been instituted, serum levels of these chemicals decrease if true vitamin B_{12} deficiency is present.

The cause of vitamin B_{12} deficiency may be determined by the use of antibody testing (anti-parietal cells and anti-intrinsic factor antibodies).[24,25] Patients with pernicious anemia are not able to absorb vitamin B_{12} because intrinsic factor is not available for binding. Some patients produce intrinsic factor but are still unable to absorb dietary vitamin B_{12}. In the elderly, malabsorption can be caused by intestinal bacteria that usurp vitamin B_{12}, achlorhydria, chronic acid suppression therapy, pancreatic insufficiency, alcohol abuse, inadequate disassociation of vitamin B_{12} from proteins, or lack of intrinsic factor receptors secondary to ileal loops, bypass, or surgical resection.[26]

PERNICIOUS ANEMIA

Signs, symptoms, and laboratory findings

CASE 92-2

QUESTION 1: C.L. is a 63-year-old Scandinavian male who is seen by a private physician. C.L. has a 1-year history of weakness and emotional instability. He also reports a painful tongue, alternating constipation and diarrhea, and a

tingling sensation in both feet. Pertinent findings on physical examination include pallor, red tongue, vibratory sensory loss in the lower extremities, disorientation, muscle weakness, and ataxia.

Significant laboratory findings include the following:

Hgb, 8.7 g/dL
Hct, 27%
MCV, 115 fL
MCH, 38 pg/cell
MCHC, 340 g/L
Reticulocytes, 0.4%
White blood cell (WBC) count, 4000/μL
Platelets, 100,000/μL
Serum iron, 90 μg/dL
TIBC, 350 g/dL
Ferritin, 140 ng/mL
RBC folate, 300 ng/mL
Serum vitamin B_{12}, 90 pg/mL
Intrinsic factor antibody positive

What signs, symptoms, and laboratory findings in C.L. are typical of pernicious anemia?

C.L.'s signs and symptoms are classic for pernicious anemia. This disease occurs equally in both sexes (primarily in individuals of northern European descent), with an average onset of age 60 years.[27] C.L.'s signs and symptoms of vitamin B_{12} deficiency include painful red tongue, loss of lower extremity vibratory sense, vertigo, and emotional instability. The elevated MCV suggests megaloblastic anemia.

Folate and iron are two other factors that can affect the MCV and should be evaluated during the workup of a patient for anemia. In this case, C.L.'s folate and iron levels are normal, but his serum vitamin B_{12} level is low. The patient's low Hgb, elevated MCV, low serum vitamin B_{12} levels, and presence of intrinsic factor antibodies are compatible with the diagnosis of pernicious anemia, which is often associated with atrophic body gastritis. The Schilling test, which confirms intestinal malabsorption of vitamin B_{12}, is no longer available in the United States.[20]

Treatment

CASE 92-2, QUESTION 2: How should C.L.'s pernicious anemia be treated? How soon can a response be expected?

C.L. should receive parenteral vitamin B_{12} in a dose sufficient to provide the daily requirement of ~2 µg and the amount needed to replenish tissue stores (about 2000–5000 µg; average, 4000 µg). To replete vitamin B_{12} stores, cyanocobalamin can be given IM in accordance with various regimens as shown in **Table 92-9**.[28] Intramuscular or deep subcutaneous administration provides improved absorption compared with rapid IV infusion. An oral tablet or intranasal cyanocobalamin solution is also available for maintenance therapy after the patient has normalized blood counts.

Table 92-9
Cyanocobalamin (Vitamin B_{12}) Supplementation Regimens for Macrocytic Anemia

Patient Population	Initial Supplementation			Chronic Supplementation (Lifelong)		
	Dose	Frequency	Route	Dose	Frequency	Route
Adults	100 µg	Daily for 7 days, then on alternate days for 14 days, then every 3–4 days for 2–3 weeks	IM or SC	100–200 µg	Monthly	IM or SQ
Severe deficiency	100–1000 µg	Daily or every other day for 1–2 weeks	IM or SC	100–1000 µg	Every 1–3 months	IM or SQ
				500 µg	Weekly	Intranasal
	1000–2000 µg	Daily for 1–2 weeks	Oral	1000 µg[a]	Daily	Oral

IM, intramuscular; SC, subcutaneous.

[a]In patients with normal gastrointestinal absorption, doses of 1–25 µg daily are considered sufficient as a dietary supplement.

Data from Facts & Comparisons eAnswers. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/home; Butler CC, Vidal-Alaball J, Cannings-John R, et al. Oral vitamin B12 versus intramuscular vitamin B12 for vitamin B12 deficiency: a systematic review of randomized controlled trials. *Fam Pract*. 2006;23:279–285.

Treatment with vitamin B_{12} should completely reverse the hematologic complications of pernicious anemia.[21,22] The reticulocyte count increases within the first week of treatment and the

megaloblastic anemia resolves within 6 to 8 weeks. Neurologic symptoms may worsen at first and then resolve over weeks to months. Some symptoms may never resolve completely. Because the rapid production of RBCs can increase potassium demand, serum potassium should be monitored, and potassium supplementation provided as necessary. Peripheral blood counts should be obtained every 3 to 6 months to evaluate the adequacy of therapy. If maintenance therapy is discontinued, pernicious anemia will recur within years, making patient adherence vital to long-term success.

Oral Vitamin B_{12}

Case 92-2, Question 3: What factors affect the oral absorption of vitamin B_{12}? When might oral vitamin B_{12} therapy be an effective alternative to parenteral therapy for C.L.?

The amount of vitamin B_{12} that can be absorbed orally from a single dose or meal ranges from 1 to 5 µg; ~5 µg of vitamin B_{12} is obtained daily from the average American diet.[22] The percentage of vitamin B_{12} absorbed decreases with increasing doses: 50% of a 1-µg dose and 5% of a 20-µg dose. Overall, oral vitamin B_{12} therapy is considered safe and effective,[29] although because of lack of long-term efficacy data, oral supplementation is not routinely used in the acute treatment of vitamin B_{12} deficiency.[26] Oral therapy for pernicious anemia using high dosages of oral cyanocobalamin may be indicated in certain patients, especially those who refuse or cannot receive other routes of therapy.[26,30] Issues of nonadherence or lack of response with oral therapy places the patient at substantial risk for significant neurologic damage. Patients receiving oral vitamin B_{12} therapy should be monitored more frequently to ensure adherence to therapy.

Anemias After Gastrectomy

CASE 92-3

QUESTION 1: F.M. has just undergone a total gastrectomy for recurrent nonhealing ulcers.

What form(s) of anemia would be expected to develop in a patient after gastrectomy? Should F.M. receive prophylactic vitamin B_{12}?

Partial or total gastrectomy often results in anemia, particularly pernicious anemia, because the loss of intrinsic factor impairs oral vitamin B_{12} absorption. The hematologic and neurologic abnormalities associated with vitamin B_{12} deficiency do not develop until existing vitamin B_{12} stores are depleted (about 2–3 years). Nevertheless, prophylactic vitamin B_{12} should be administered in this patient after total gastrectomy.[31] Because the vitamin B_{12} stores are not currently depleted, maintenance therapy, as discussed in Case 92-2, Question 2, should be adequate for F.M.

Anemias After Gastric Bypass

CASE 92-4

QUESTION 1: P.G. is a 48-year-old female scheduled to have laparoscopic Roux-en-Y gastric bypass (RYGB) surgery for morbid obesity with a body mass index (BMI) >40.

What forms of anemia would be expected to develop in P.G.?

When an RYGB procedure is performed, the stomach is decreased in size, and the small intestine is manipulated creating a gastrojejunostomy and jejunojejunostomy.[32] This results in bypassing the duodenum and proximal jejunum where iron is absorbed, resulting in iron deficiency anemia. The gastric pouch is no longer an acidic environment which impairs iron bioavailability and functioning of iron transport mechanisms. Patients are also recommended to avoid red meat, which is a common dietary source of iron. An acidic environment is also needed for the bioavailability of vitamin B_{12}

leading to decreased absorption. The diagnosis of vitamin B_{12} deficiency following bariatric surgery is rare because of the large amount stored in the body. Folate deficiency may occur from reduced dietary folate intake. The majority of folate is absorbed from the upper third of the small intestine but may occur at any location. Iron deficiency anemia is the most common cause of anemia in bariatric surgery patients; however, other micronutrient deficiencies may also contribute.

CASE 92-4, QUESTION 2: What prophylactic strategies might P.G. employ to prevent anemia?

Following bariatric surgery, patients will need to take lifelong multivitamin and micronutrient supplementation.[33] Patients should take a high-potency multivitamin with 100% of the recommended daily value for at least 75% of the nutrients. It should have a minimum of 18 mg iron, 400 µg folic acid, selenium, and zinc.[34] Patients should be instructed to take an additional one to two tablets per day of an iron salt, ferrous sulfate, or ferrous fumarate to prevent iron deficiency anemia. In addition to a high-potency multivitamin, patients should take 350 to 500 µg/day of oral cyanocobalamin or receive 1000 µg injections monthly.

Folic Acid Deficiency Anemia

FOLIC ACID METABOLISM

Folate is abundant in virtually all food sources, especially fresh green vegetables, fruits, yeast, and animal protein. As a result of food fortification, the average American diet provides 50 to 2000 µg of folate per day; however, excessive or prolonged cooking (>15 minutes) in large quantities of water may reduce the folate contained in food.[35] Human requirements for folate vary with age and depend on the rate of metabolism and cell turnover but are generally 3 µg/kg/day.[35] The minimal daily adult requirement of folate is 50 µg but, because absorption from food is incomplete, a daily intake of

200 µg is recommended. Folate requirements are increased in conditions in which the metabolic rate and rate of cellular division are increased (eg, pregnancy, infancy, infection, malignancies, hemolytic anemia). The following are estimates of daily folate requirements based on age and growth demands: children, 80 to 400 µg; infants, 65 µg; and pregnant or lactating females, 600 µg.[36]

Dietary folic acid is in the polyglutamate form and must be enzymatically deconjugated in the GI tract to the monoglutamate form before it is absorbed. Once absorbed, the inactive dihydrofolate must be converted to active tetrahydrofolate (folinic acid) by dihydrofolate reductase.

In contrast to the large stores of vitamin B_{12}, the body's folate stores are relatively small (about 5–10 mg). Therefore, deficiency and subsequent megaloblastic anemia can occur within 3 to 4 months of decreased folate intake.

PREDISPOSING FACTORS

Folate deficiency is most commonly associated with alcoholism, rapid cell turnover, and dietary deficiency. In alcoholics, the daily intake of the folate contained in food may be restricted or absent. In addition, enterohepatic recirculation of folate can become impaired by the toxic effect of alcohol on hepatocytes. Folate deficiency may also develop during the third trimester of pregnancy as a result of a marginal diet and rapid fetal metabolism. Folate coenzymes are required for most metabolic pathways (**Fig. 92-2**). Therefore, folate deficiency will develop in any condition of rapid cellular turnover (eg, hemolytic anemias, hemoglobinopathies, sideroblastic anemia, leukemias, lymphomas, multiple myeloma) or a diet lacking in folate (eg, food faddism or a weight-loss diet). Folate deficiency also can occur with chronic hemodialysis, diseases that impair absorption from the small intestine (eg, sprue, regional enteritis), extensive jejunal resections, and drugs that alter folate metabolism (eg, trimethoprim, pyrimethamine, methotrexate, sulfasalazine, oral contraceptives, anticonvulsants).[37,38] Few patients have inborn errors of folate metabolism.[39]

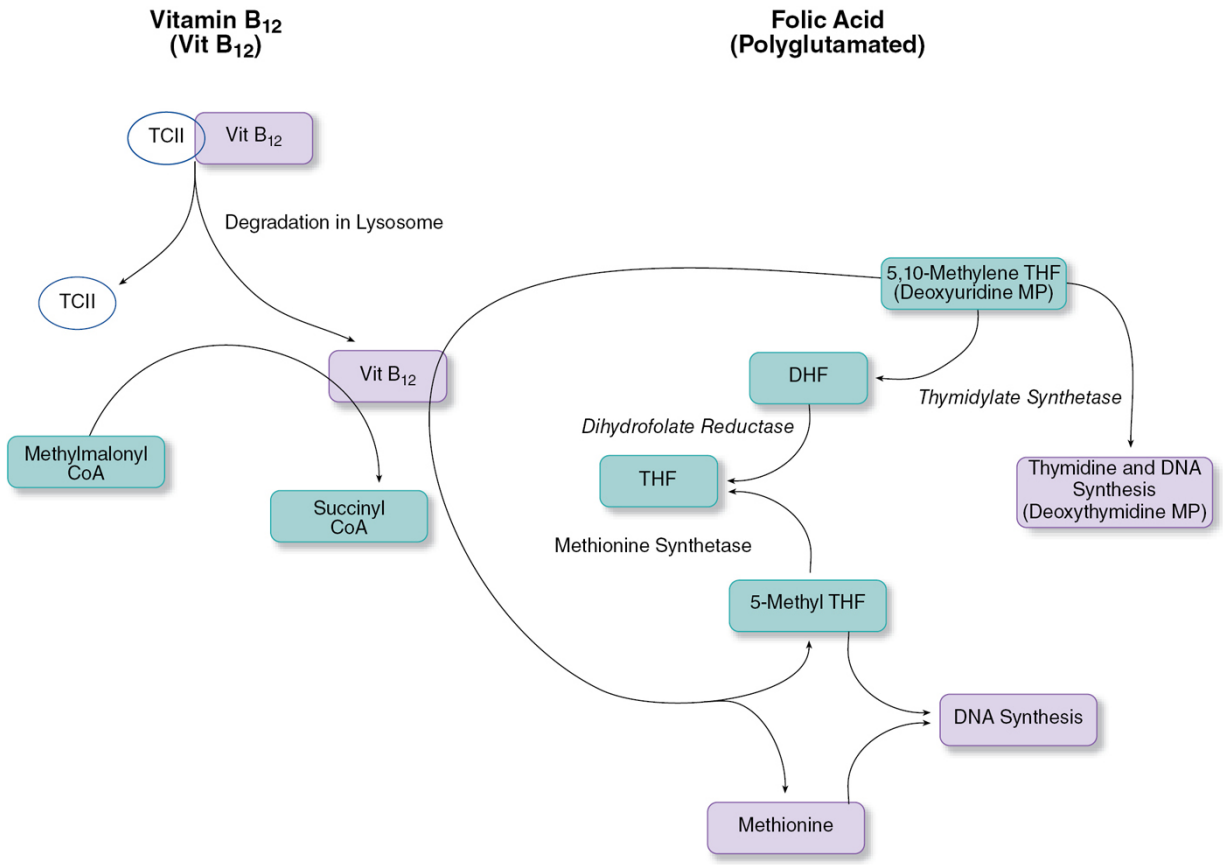

Figure 92-2 Intracellular metabolic pathways. Both vitamin B_{12} and folic acid are necessary for nucleic acid precursors used for DNA synthesis. DHF, dihydrofolate; MP, monophosphate; TCII, transcobalamin II; THF, tetrahydrofolate.

The evaluation of megaloblastic anemia must be thorough because indiscriminate use of nondirected therapy can be dangerous. Large doses of folate can partially reverse hematologic abnormalities caused by vitamin B_{12} deficiency; however, folate cannot correct neurologic damage caused by vitamin B_{12} deficiency. Therefore, folate deficiency must be differentiated from vitamin B_{12} deficiency *before* folate therapy is initiated. Otherwise, progression of the neurologic sequelae of vitamin B_{12} deficiency can occur.

CASE 92-5

QUESTION 1: D.H. is a malnourished-appearing female in her second trimester of pregnancy who presents to the local health clinic for her regular checkup. She is a multiparous, 26-year-old female with a 7-year history of excessive alcohol intake and has been using cocaine frequently for 3 years. She lives with her boyfriend and her 19-month-old daughter. During both pregnancies, D.H. lost 8 to 10 pounds (3.63–4.54 kg) during the first trimester secondary to nausea, vomiting, and anorexia. Her only problems are dyspnea on exertion, palpitations, and diarrhea.

Pertinent laboratory values include the following:

Hct, 25.5%
MCV, 112 fL
MCH, 34 pg/cell
RBC, 1.1 × 10^6/μL
Iron, 179 μg/dL
Folate, 40 ng/mL
Serum vitamin B_{12}, 350 pg/mL (normal, 200–1000)
Reticulocytes, 1%
Platelets, 70,000/μL
WBC count, 2000/μL with hypersegmented polymorphonuclear neutrophils (PMNs)
Lactate dehydrogenase (LDH), 425 units/L
Bilirubin, 1.2 mg/dL
D.H. is not taking any prescription medications.

What factors make D.H. at risk for folate deficiency?

As with most patients who are folate-deficient, D.H. has more than one risk factor. Cocaine and alcohol, together with multiparity complicated by anorexia, nausea, and vomiting, could lead to poor nutrition. Alcohol has toxic effects on the intestinal mucosa and interferes with folate utilization by the bone marrow. D.H. should be asked specifically about her dietary habits and recent weight history. She may have a folate-poor diet for financial reasons or because she is overcooking her food. Alternatively, cocaine may be causing anorexia. The nutritional intake of people who abuse alcohol and drugs is often poor. The diagnosis of folate deficiency is plausible, considering folate deficiency can develop in a matter of weeks to months.

DIAGNOSIS AND MANAGEMENT

CASE 92-5, QUESTION 2: Which laboratory values support the diagnosis of folate deficiency? How should D.H. be treated and monitored?

D.H.'s laboratory values reflect macrocytic anemia (Hct, 25.5%; MCV, 112 fL) with pancytopenia (reduced number of RBCs, WBCs, and platelets). Serum vitamin B_{12} concentrations reflect normal vitamin B_{12} stores, but folate stores are inadequate as exemplified by the low RBC folate concentration, pancytopenia, and macrocytic anemia.

Serum folate concentrations generally reflect folate balance during the past 3 weeks although one balanced meal can raise serum levels and falsely elevate body stores. Tissue folate stores are more accurately reflected by the RBC polyglutamated folate content, which is ~10 to 30 times the corresponding serum folate concentrations.[40] Hemolysis or vitamin B_{12} deficiency causes leakage of monoglutamated folates from cells, thereby falsely elevating serum folate levels.[41]

D.H. should be counseled regarding her nutritional and social habits. Because the estimated total-body folate store is only about 5 to 10 mg, 1 mg of folic acid given daily for 2 to 3 weeks should be more than adequate to replace her storage pool of folate. Higher dosages (up to 5 mg) may be needed, however, if absorption is compromised by alcohol or other factors.[37] Once stores are replenished, D.H. should continue folate supplements throughout her pregnancy and lactation period. She should be reassessed after the course of therapy to determine the response to therapy and whether the cause of the folate deficiency has been corrected. Supplementation with folic acid 1 mg/day may be required as long as risk factors are present. D.H.'s fetus is unlikely to develop folate deficiency because maternal folate is preferentially delivered to the fetus; however, sustained folate deficiency during pregnancy can cause birth defects in the newborns (see Chapter 49, Obstetric Drug Therapy).

D.H.'s response to therapy can be monitored by several different parameters. Although bone marrow aspirates are not obtained

routinely, the RBC morphology should begin to revert to normal within 24 to 48 hours after therapy is initiated, and hypersegmented neutrophils should disappear in the periphery in about 1 week. Serum chemistry and hemogram studies should begin to normalize within 10 days. The reticulocyte count should increase by day 2 to 3 and peak by day 10. Bilirubin and LDH values should normalize in 1 to 3 weeks. Finally, the anemia should be corrected in 1 to 2 months. Once anemia is corrected, 100 µg daily of folate as a nutritional supplement should be adequate for maintenance treatment (independent of the patient's pregnancy/lactation status).

SICKLE CELL ANEMIA

Pathogenesis

Sickle cell anemia is an inherited, autosomal recessive hemoglobin (Hgb) disorder characterized by mutations in the β-globin gene. Hemoglobin S (HbS) results from a DNA substitution of thymidine for adenine in the glutamic acid codon, forming a B6 valine instead of glutamic acid.[42,43] The Hgb produced from this substitution has a more negative charge than normal adult hemoglobin (HbA) and in the deoxygenated state will aggregate and polymerize, forming sickled RBCs. Sickled RBCs are more rigid and when passing through the microvasculature adhere to activated vascular endothelial cells, resulting in vascular occlusions. Additionally, sickled RBCs also adhere to macrophages leading to erythrophagocytosis and hemolysis, a clinical feature associated with the diagnosis of sickle cell anemia.[43]

More than one inheritance pattern results in abnormal Hgb polymerization. Patients with sickle cell anemia are homozygous, inheriting a sickle gene from each parent (HbSS), whereas patients with sickle cell trait are heterozygous and have inherited the sickle cell gene from one parent and the HbA gene from the other parent (HbAS). Other inheritance patterns include patients with HbSC, a

sickle cell gene, and a hemoglobin C gene (HbC) where the glutamic acid is substituted for a B6 lysine. Patients may also inherit the sickle cell gene and a β-thalassemic gene (HbS-β+ thalassemia or HbS-β^0 thalassemia). HbSS is the most common and most severe type of sickle cell disease. HbSC is the second most common form but is associated with less severe symptoms. In general, most other forms of this disease, including HbS-β+ thalassemia, are associated with mild-to-moderate symptoms with the exception of HbS-β^0 thalassemia, which exhibits more severe disease similar to HbSS.[42,44]

Sickle cell disease genotypes can be found in a large number of ethnic groups because of genetic admixture. However, the disease is more prevalent in regions of sub-Saharan Africa, the Mediterranean basin, Middle East, and India but can also be found in relatively high numbers in the Americas and Caribbean.[42,44] In the United States, roughly 1 in 13 Blacks is born with sickle cell trait, and ~100,000 people have sickle cell disease.[45]

Laboratory Evaluation

When evaluating a patient for sickle cell disease, the laboratory workup should include a CBC, reticulocyte count, peripheral blood smear, and hemoglobin electrophoresis. Those diagnosed with sickle cell anemia most commonly have elevated WBC and platelet counts in addition to anemia resulting from decreased hemoglobin and hematocrit. The reticulocyte count is frequently elevated, the degree to which varies based on the level of anemia and hemolysis. The MCV may also be elevated. If MCV values are low or within the normal range, iron deficiency or other forms of sickle cell disease must be considered. Sickled cells may be visually observed by a peripheral blood smear in poorly oxygenated blood of a patient with sickle cell anemia. Hemoglobin electrophoresis is used to identify the presence of HbSS in sickle cell anemia and can help determine other hemoglobinopathies (eg, HbSC). In contrast, a patient with the sickle cell trait should have normal RBC morphology (sickled cells

are rarely observed) and normal WBC, reticulocyte, and platelet counts.[44]

Clinical Course and Management

In an effort to improve outcomes in this population, routine screening for sickle cell anemia or sickle cell trait is performed on all newborns in the United States. Therefore, unless born outside of the United States, the majority of patients are diagnosed during their first year of life. Families carrying sickle cell trait or disease are referred for genetic counseling. Patients with sickle cell disease are referred to a hematologist and multidisciplinary team for medical management.

The clinical signs of sickle cell disease typically appear after age 6 months, when fetal hemoglobin levels fall to a point where abnormalities associated with HbS can present. Complications from sickle cell disease persist for the life of a patient. The prognosis for patients diagnosed with this disease is uncertain as morbidity is variable and mortality is high, particularly in childhood. With the advent of better treatment, studies demonstrate survival is improving but life expectancy remains about 30 years less than the general population.[42]

The management of sickle cell disease is largely directed toward prophylaxis against infections and supportive management of vaso-occlusive crises. The clinical course among patients with sickle cell disease is variable and difficult to predict. Some patients experience a multitude of health problems. Organs such as the kidneys, retina, spleen, and bones are frequent sites of vaso-occlusive events because of relatively low pH and oxygen tension. Cardiac, pulmonary, neurologic, hepatobiliary, obstetric/gynecologic, ocular, dermatologic, or orthopedic complications can also occur. The management of these complications is organ-specific and primarily aimed at supportive interventions.

INFECTIONS

CASE 92-6

QUESTION 1: B.C. is a 4-month-old female who has recently been diagnosed with sickle cell anemia (both parents positive for sickle cell trait). Her older sibling is positive for sickle cell trait but is asymptomatic.

How does B.C.'s diagnosis affect her risk of infections?

B.C. is at an increased risk for infections because sickle cell anemia causes defects in splenic function, complement activation, granulocyte function, and B-cell immunity, as well as micronutrient deficiencies.[46] Impaired splenic function because of splenic sequestration results in vaso-occlusion and increases B.C.'s risk for infection from polysaccharide-encapsulated bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*, and *Salmonella typhimurium.*[47,48] These types of infections occur most frequently in early childhood because 94% of sickle cell anemia patients have functional asplenia by age 5 years. It is important to note that patients like B.C. will have a lifelong increased risk of infection. Pneumonia caused by *S. pneumoniae,* mycoplasma, or viruses can worsen hypoxia, causing progression to vaso-occlusion and acute chest syndrome (discussed in more depth below). Other infectious conditions such as osteomyelitis from *Staphylococcus aureus* or *S. typhimurium* or urinary tract infections caused by *Escherichia coli* are common complications in patients with sickle cell anemia.[47]

CASE 92-6, QUESTION 2: What preventive measures should be taken to prevent infections in B.C.?

Patients with sickle cell anemia should use general preventive measures, such as frequent handwashing, avoiding sick contacts, and thoroughly cooking foods that may carry *Salmonella* (eg, chicken or eggs).[46] Children should be closely monitored for symptoms, and antibiotic therapy should be instituted at the earliest sign of infection. Prophylactic administration of penicillin has significantly reduced morbidity and mortality from pneumonia in

children younger than 3 years of age and is recommended to be continued through age 5.[47,49] Patients such as B.C. should receive 125 mg orally twice daily for ages 1 through 3, then 250 mg orally twice daily until age 5. Guidelines recommend discontinuing penicillin prophylaxis at age 5 unless the child has undergone splenectomy or has had an invasive pneumococcal infection.[49]

Patient with sickle cell anemia should receive all guideline-recommended pediatric and adult vaccines. In addition to the standard pneumococcal conjugate vaccine series, at 2 years old, B.C. should receive the pneumococcal 23-valent polysaccharide vaccine no earlier than 8 weeks after any pneumococcal 13-valent conjugate vaccine and another dose 5 years later.[50] Pediatric patients with sickle cell disease should additionally receive meningococcal prophylaxis per vaccine recommendations using the appropriate dose and schedule based on the meningococcal vaccine given. It is important to note that live attenuated influenza vaccine is contraindicated in sickle cell patients.[50]

Vaso-occlusive Complications

CASE 92-7

Question 1: J.T. is an 18-year-old male with sickle cell anemia who presented to the emergency department with rapid onset of abdominal pain and shortness of breath. During early childhood, he experienced several episodes of acute pain, swelling of the hands and feet, and jaundice. Three years before this admission, J.T. required a left hip replacement because of osteonecrosis caused by sickle cell anemia. Recently, frequent blood transfusions have reduced the frequency of sickling crises.

Physical examination reveals J.T. as a thin, Black male in acute distress and with scleral icterus. He has a pulse of 118 beats/minute, a respiratory rate of 17 breaths/minute, and a temperature of 98.8 °F (37.11 °C). His lungs are clear. Splenomegaly is noted, and a chest radiograph reveals only cardiomegaly.

A CBC is obtained. Notable results include the following:

Hgb, 5.9 g/dL
Hct, 27%
WBC count, 5000/μL
Platelets, 335,000/μL

Reticulocyte count, 1%
Bilirubin, 5.8 mg/dL
Serum creatinine, 3.1 mg/dL
Blood urea nitrogen, 54 mg/dL
The peripheral blood smear shows target cells with an occasional sickle cell.

What signs and symptoms are consistent with sickle cell anemia? What is J.T.'s current complication?

Vaso-occlusive crisis is caused by severe pain and organ damage. These may be precipitated by many factors including hypoxia, dehydration, infection, and pregnancy.[51] Based on the presence of splenomegaly, anemia, and sickled cells, J.T. currently is presenting with an acute splenic sequestration crisis. Acute splenic sequestration is caused by the trapping of RBCs within the spleen. This causes splenomegaly and progressive anemia. The low reticulocyte count is consistent with acute sequestration as a reticulocyte response would be expected if the anemia had developed in recent days. J.T.'s inadequate reticulocyte response may reflect rapid progression of the anemia, HPV B19 infection (a common cause of transient RBC aplasia, with up to 67% of infections resulting in a hematologic change typical of aplasia), or a blunted EPO response secondary to compromised renal dysfunction.

Case 92-7, Question 2: How should J.T. be treated?

J.T.'s signs and symptoms are sufficiently serious to justify transfusion therapy. The goal of transfusion in this setting is to correct hemoglobin levels to baseline and avoid hyperviscosity and cardiovascular sequelae.[51] In addition, J.T. should be adequately hydrated, considering his elevated serum creatinine and blood urea nitrogen. Because patients with sickle cell anemia often lose the ability to concentrate urine, they may become dehydrated, which further contributes to cell sickling. The pain associated with a crisis typically lasts at least 2 to 6 days and should be managed with analgesics, including parenteral opioids for severe pain. Pain control should be rapidly and aggressively instituted for J.T.'s comfort and

should be continued for a few days after hospital discharge. It is important not to withhold opioids because of a fear of addiction.[52]

Splenectomy may be indicated in instances of severe splenomegaly, repeated infarction, or pain in adults, and it is indicated when crises occur in children. Those patients with sickle cell anemia who are bedridden should be placed on anticoagulation to prevent vascular occlusions and deep vein thrombosis.

Case 92-7, Question 3: J.T. presents to the emergency department 3 months later with fever, cough, and severe throbbing pain in his chest and abdomen beginning 2 days prior. This is his third admission within the last year. Notable laboratory results include the following:

Hgb, 6.6 g/dL
Hct, 18.9%
Platelets, 218,000/μL
WBC, 19,700/μL
Bilirubin, 4.7 mg/dL
Serum creatinine, 1.1 mg/dL

His chest radiograph shows diffuse interstitial infiltrates in both lung fields. His vital signs are as follows: blood pressure, 98/53 mm Hg; heart rate, 102 beats/minute; respiratory rate, 23 breaths/minute; temperature, 101.4 °F (38.55 °C); and oxygen saturation, 93%. What complication of sickle cell disease is J.T. experiencing and how should he be treated for this condition?

J.T. is experiencing acute chest syndrome, a leading cause of morbidity and mortality in patients with sickle cell disease. The diagnosis of acute chest syndrome is determined by new pulmonary infiltrates on chest radiograph with one or more of the following: fever, cough, respiratory symptoms, worsening anemia, and pleuritic or nonpleuritic chest pain.[48] Causes of acute chest syndrome include pulmonary fat embolism, pulmonary infarction, and infection.[53] Commonly implicated organisms include *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, *S. pneumoniae*, *Haemophilus influenzae*, and various viruses.

The primary goal of treatment is to prevent progression to acute respiratory failure; therefore, treatment should involve pain management, hydration, oxygen supplementation, incentive

spirometry, antibiotics and, potentially, transfusion.[49,53] Optimal pain control and incentive spirometry are important to prevent hypoventilation and atelectasis, as well as to increase patient comfort. Oxygen should be administered nasally to patients who are moderately hypoxemic (O_2 saturation, 92%–95%; Pa_{O_2}, 70–80 mm Hg), as J.T. is. Patients who are febrile or severely ill should receive IV broad-spectrum antibiotics as it is difficult to exclude bacterial causes of acute chest syndrome. Empiric antibiotic therapy should consider the commonly implicated organisms described above.

Transfusions are used to increase the oxygen affinity of blood and are indicated in patients with worsening radiographic or clinical status, an Hgb 10% to 20% below baseline or below 5 g/dL, or hematocrit that is dropping.[44,53] J.T. should be monitored closely for deteriorating respiratory function and should receive transfusions if his clinical status does not improve.

TREATMENT FOR FREQUENT VASO-OCCLUSIVE CRISES

Case 92-7, Question 4: What preventive therapies exist for J.T. that will reduce occurrences of vaso-occlusive crises?

Currently, there are four FDA-approved agents for the treatment of sickle cell disease: their dosing and adverse effects are summarized in **Table 92-10**. Hydroxyurea, the oldest, is a first-line agent that increases fetal hemoglobin (HbF) synthesis, which has been found to decrease RBC sickling and the occurrence of disease-related complications.[44,51] In fact, patients with HbF levels >20% have been shown to experience a relatively mild or benign disease course with fewer vaso-occlusive crises.[51] Hydroxyurea is given prophylactically in patients with recurrent moderate-to-severe vaso-occlusive crises; not as an acute treatment. Guidelines recommend hydroxyurea for children (>2 years) and adult patients who have three or more sickle cell-associated moderate-to-severe pain crises in a 12-month period, severe or recurrent acute chest syndrome, chronic pain that interferes with quality of life, or symptomatic anemia.[48] These

recommendations are based on several clinical trials where hydroxyurea demonstrated improvement in the clinical course of patients with sickle cell anemia.[51] The use of hydroxyurea should be weighed for risk versus benefit because it is a cytotoxic agent. Monitoring of blood counts should occur to allow for dose adjustments of hydroxyurea based on efficacy and tolerability. Other adverse effects of hydroxyurea include fertility issues, GI effects (nausea, vomiting, diarrhea), dermatologic effects (maculopapular rash, pruritus), and potential risk of developing a secondary neoplasm (leukemia) with prolonged use.

Table 92-10
FDA-Approved Sickle Cell Anemia Therapies

Medication	Dose	Frequency	Route	Common Adverse Effects	Notes
Hydroxyurea	15–35 mg/kg (titrate to tolerated dose)	Once daily	Oral (tablet and liquid)	*Common:* Eczema (infants and children) Macrocytosis Neutropenia Infection	Take with food Dose reduction in patients with renal dysfunction
L-Glutamine	10–30 g	Twice daily	Oral powder	*Common:* None	Mix dose in 240 mL cold or room temperature beverage or with 4–6 oz of semisolid food (ie, applesauce, yogurt) Prepare immediately prior to administration
Voxelotor	1500 mg	Once daily	Oral tablet (including tablet for oral suspension)	*Common:* Abdominal pain Diarrhea Fatigue Fever Headache Nausea Skin rash	Dose reduction in patients with severe hepatic impairment (Child–Pugh C) Avoid concomitant use of strong or moderate CYP3A4 inducers.
Crizanlizumab	5 mg/kg	Every 2 weeks for first three doses then monthly	IV	*Common:* Arthralgia Back pain Fever Infusion-related reaction Nausea	Monitor for infusion-related reactions May interfere with automated platelet counts (platelet clumping); collect blood in citrate-containing tubes

Source: Data from Facts & Comparisons eAnswers. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/home

More recently, three other medications have been approved for the treatment of sickle cell disease and may be given alone or with hydroxyurea. L-Glutamine is an amino acid used in the production of proteins. It is an oral therapy indicated for use in both children (>5 years) and adults with sickle cell disease. The exact mechanism is

unclear, but it may reduce oxidative injury, especially in times of stress when the body uses more glutamine.[44] Clinical studies showed that L-glutamine use reduced the frequency and severity of vaso-occlusive crises as well as hospitalizations.[44,48] It is given orally, does not require monitoring, and has minimal side effects but is quite costly, which introduces barriers to use.

Voxelotor, an HbS polymerization inhibitor, is approved for use in sickle cell patients ages 12 years and older. This oral therapy has been shown to improve anemia and decrease transfusion in patients. The data on the impact of the drug on vaso-occlusive events are mixed. The most common adverse events with voxelotor is mild-to-moderate arthralgia, headache, pain, nausea, and pain in the extremity.[54,55] Crizanlizumab is a monoclonal antibody that binds to P-selectin (a glycoprotein found on activated endothelial cells and platelets) to prevent the occurrence of vaso-occlusive crises. Results from a study investigating the use of crizanlizumab in patients with sickle cell disease showed that it significantly lowered the rate of sickle cell–related pain crises and was associated with fewer adverse events compared to placebo. More common adverse events associated with use include arthralgia, diarrhea, pruritus, vomiting, and chest pain.[56] Crizanlizumab is given as an intravenous infusion and is only approved in patients ages 16 years and older. Of note, none of the three more recent FDA-approved agents has been shown to alter end-organ damage or lesson symptoms other than pain.[44] Other areas of potential promise for the treatment of sickle cell anemia include bone marrow transplantation and gene therapy.[48]

IRON CHELATION THERAPY

CASE 92-7

QUESTION 5: Despite optimal treatment with hydroxyurea, J.T. continues to experience exacerbations of his sickle cell disease requiring blood transfusions. J.T. estimates he has required six such transfusions in the last 2 years and at least 25 units of blood in his lifetime. During a visit with his hematologist, J.T.'s serum ferritin is noted to be 1050 µg/L. What potential adverse effect of

treatment is the hematologist's concern? What other tests may be performed to detect this?

Transfusions are the mainstay of treatment for the majority of patients with sickle cell disease. Those requiring chronic transfusions of packed red blood cells (PRBCs) are at an increased risk for iron toxicity because of iron overload.[51] Normally, plasma iron binds with transferrin; however, if transferrin becomes saturated, patients will have higher levels of toxic nontransferrin-bound iron. As nontransferrin-bound iron increases, it deposits in other organs, most frequently the liver, and produces free radicals, causing tissue damage and fibrosis.

Patients with sickle cell disease should be monitored for iron overload. Obtaining a serum ferritin level is the most commonly used method of screening for iron overload, although the accuracy of this test is affected by inflammatory processes. Thus, serial serum ferritin values should be obtained when patients are not experiencing an acute crisis (ie, steady-state values). More specific tests, such as magnetic resonance imaging, measure iron levels in organs such as the heart, liver, pancreas, and spleen, although may not be routinely used because of cost.[51]

CASE 92-7

QUESTION 6: J.T. returns for continued assessment of iron overload. His repeat serum ferritin levels are 1357 and 1500 µg/L (3 months apart). Liver iron concentration is 7.8 mg/g dry weight. Does J.T. meet the criteria to receive iron chelation therapy? What options are available?

J.T. meets the criteria for iron chelation therapy because of his steady-state serum ferritin levels being consistently >1000 µg/L and his liver iron concentration being >7 mg/g dry weight.[49] Other considerations for a patient to receive iron chelation therapy include transfusion of ~100 mL/kg of PRBCs or 20 units for a 40-kg or more patient.

There are three iron chelators currently approved for use in patients with sickle cell disease. These agents work by binding free iron present in circulation and tissues. The iron is then excreted in the urine and bile.

Deferoxamine (DFO) and deferasirox have been studied in patients with sickle cell disease who are as young as 2 years old; deferiprone is approved for use in patients ages 8 years and more. Because of its short half-life, DFO must be administered for 5 days via continuous IV or subcutaneous infusion.[57] Deferasirox has a longer half-life, allowing for once-daily oral administration and enhanced patient convenience and adherence.[58] Deferiprone is also an oral agent and can be dosed two or three times per day.[59] In a meta-analysis looking at the effect of iron chelation therapy in sickle cell disease, its use resulted in better overall survival and event-free survival in transfusion-dependent patients. These outcomes were enhanced when iron chelation therapy was instituted early, and compliance was maintained. The analysis did not find any significant differences between the three available iron chelation agents; however, it showed that deferiprone is better tolerated than DFO, and compliance was improved with the two oral drugs.[60] Based on these data, deferiprone or deferasirox are appropriate for J.T. at this time.

J.T. should also receive appropriate monitoring consisting of serial serum ferritin levels and annual audiology and ophthalmology assessments as audiometric and retinal toxicity can be associated with overchelation. Patients receiving deferasirox should have serum creatinine monitored weekly for the first month after initiation or a dose alteration and monthly thereafter.[49] Because of the risk of agranulocytosis, ANC should be monitored weekly for the first 6 months of therapy, then every 2 weeks for the next 6 months, followed by every 2 to 4 weeks thereafter. Additionally, routine assessment of liver function tests should also be initiated for all patients receiving iron chelation therapy.

Other Complications of Sickle Cell Disease

NEUROLOGIC COMPLICATIONS

Neurologic complications are age dependent. Stroke most commonly occurs in the first decade of life, whereas intracerebral hemorrhage is a complication associated with adulthood. Primary prevention of stroke with RBC transfusions targeted to maintain HbS level <30% reduces the incidence of stroke in high-risk patients by 92%.[51] If a stroke occurs, ~50% of patients experience recurrent strokes within 3 years unless they are treated by chronic RBC transfusion therapy.[51]

RENAL AND GENITAL COMPLICATIONS

Renal and genital complications are common in sickle cell disease because the environment (hypoxic, acidotic, and hypertonic) predisposes the renal medulla or corpus cavernosum to infarction. As a result, patients might experience reduced potassium excretion, hyperuricemia, hematuria, hyposthenuria, and renal failure. Patients with renal disease generally have inappropriately low levels of EPO as well. Males experiencing occlusion of the corpus cavernosum can experience acute or chronic priapism. Conservative management includes IV fluid administration and pain control. Chronic unmanaged priapism increases the risk for erectile dysfunction and impotence.[44,48]

MICROINFARCTIONS

Microinfarctions often produce ophthalmic, hepatic, orthopedic, and obstetric/gynecologic complications as well. Patients with sickle cell anemia may require screening to detect these complications.[49]

ANEMIA OF INFLAMMATION

Anemia of inflammation (AI), also known as anemia of chronic disease, refers to a mild-to-moderate anemia that results from decreased RBC survival and production and generally occurs over

months to years.[61] It has been associated with a number of disorders (eg, autoimmune disorders, acute and chronic infections, chronic kidney disease, and malignancy). Because of the common occurrence of such conditions, AI is estimated to be the second most common anemia after iron deficiency. Most often, AI is a normochromic, normocytic anemia, although RBCs may be hypochromic and microcytic in some patients. A prominent feature of AI is the altered availability of iron, which is not reliably reflected in iron indices because of IL-6 and other cytokines stimulating an increase of hepcidin, a hormone that regulates iron homeostasis and influences iron absorption as well as the release of iron stores. Cytokines also result in an inadequate EPO response for the degree of anemia. A shortened RBC life span also contributes to AI, because of enhanced phagocytosis of RBC; this is because of enhanced “bystander” deposition of antibody and complement, mechanical damage to the RBC, and increased macrophage activation.

In AI, serum iron, transferrin saturation, and TIBC are low with an increased serum ferritin. Conversely, in iron deficiency anemia, serum iron, transferrin saturation, and serum ferritin are low with an increased TIBC. However, it is important to recognize that both forms of anemia may be seen concurrently.

Management of mild-to-moderate AI usually focuses on the underlying disease process. AI is not usually progressive or life-threatening but affects the quality of life. Patients may require blood transfusions for symptomatic anemia, which are associated with risks such as hepatitis, viral infections, iron overload, treatment-related acute lung injury, and immunogenic reactions. Unless a concurrent vitamin deficiency exists, administration of vitamin supplements for AI is not of value. Iron supplementation may be warranted in patients with a functional or absolute iron deficiency anemia. Erythropoiesis-stimulating agents (ESAs) have been used successfully to treat AI in patients with rheumatoid arthritis, acquired immunodeficiency syndrome (AIDS), malignancy, and chronic kidney disease; however, medication costs and safety risks, including

increased mortality, should be considered when selecting treatment.[61]

Erythropoietic Therapy

Erythropoietic therapy is indicated for use in anemia associated with chronic kidney disease, drug-induced anemia (see **Table 92-11**), and to reduce allogeneic RBC transfusions for elective noncardiac, nonvascular surgery.[62–64] Response to ESAs is dependent on dose and the underlying cause of anemia and may take days to weeks. Currently, there are two ESAs, epoetin alfa (Procrit®, Epogen®) and darbepoetin alfa (Aranesp®), approved for use in the United States. Darbepoetin differs from epoetin alfa by the addition of two carbohydrate chains, which result in decreased clearance and a serum half-life three times longer than that of epoetin alfa. These kinetic differences allow darbepoetin alfa to be administered less frequently (Table 92-11). Lack of response to erythropoietic therapy (ESA hyporesponsiveness) in all patient populations is most commonly associated with concurrent iron deficiency.

Table 92-11
Therapeutic Uses and Regimens for Recombinant Human Erythropoietin (rhEPO)[a]

	Epoetin Alfa		Darbepoetin Alfa	
Anemia Pathogenesis	**Dose (Units/kg)**	**Frequency**	**Dose (μg/kg)**	**Frequency**
Zidovudine-induced	100	Three times per week	—	—
Chemotherapy-induced	150 or 40,000 units (total dose)	Three times per week or once a week, respectively	2.25 or 500 μg (total dose)	Once a week or once every 3 weeks, respectively
Chronic kidney disease	50–100	Three times per week	On dialysis 0.45 or 0.75 Not on dialysis 0.45	Once a week or once every 2 weeks, respectively Once every 4 weeks

[a]Adult dosing.

Although some studies assessing the use of ESAs in the treatment of chronic kidney disease and chemotherapy-induced anemia (CIA) have shown decreased RBC transfusions, there is also evidence that use increases the risk for cardiovascular events, stroke or thrombosis, shortens overall survival, and/or increases the risk of

tumor progression or recurrence in some patient populations.[62–64] Health care providers are encouraged to discuss the risks and benefits of using ESAs with each patient prior to initiating use.

Luspatercept-aamt (Reblozyl®) is an erythroid maturation agent used to reduce RBC transfusion requirements in patients with β-thalassemia or in patients with low-intermediate risk myelodysplastic/myeloproliferative syndromes with ringed sideroblasts who have failed prior treatment with an ESA (see Chapter 96, Adult Hematologic Malignancies).[65] Similar to the ESAs, luspatercept-aamt should be titrated based on transfusion requirements and Hgb response and is not effective in the short-term (ie, should not be used as a substitution for patients needing immediate RBC transfusions). There is an increased risk of hypertension and thrombosis/thromboembolic events with this agent; thus, patients should continue to be closely monitored while receiving this therapy. Luspatercept-aamt must be administered by a health care provider, unlike the ESAs which may be self-administered.

Renal Insufficiency–Related Anemia

The cause of renal insufficiency–related anemia is complex but involves reduced EPO production and a shortened RBC life span. Repeated transfusions are a possible treatment but can lead to complications and should be avoided unless rapid Hgb correction is needed. Because EPO is secreted in the kidney in response to anoxia and is responsible for normal differentiation of RBCs from other stem cells, erythropoietic therapy is used to treat anemia in patients with renal failure who are undergoing hemodialysis.[66,67] A dose-dependent rise in Hct is observed in patients with end-stage renal disease at approved doses of epoetin alfa or darbepoetin alfa (see Table 92-11). Targeting higher concentrations of Hgb (>13 g/dL) is associated with increased mortality and adverse effects. An FDA-mandated black-box warning for these drugs states that treatment should be individualized to maintain use of the lowest dose of an

ESA necessary to decrease the need for transfusion.[62–64] This target Hgb differs from the current kidney disease guidelines.[66,67] Refer to Chapter 28, Chronic Kidney Disease, for further information on treatment target goals as well as the appropriate use of ESAs and IV iron in patients with renal insufficiency–related anemia.

Malignancy-Related Anemia

CASE 92-8

Question 1: P.M. is a 62-year-old female diagnosed with stage IV ovarian cancer. She is being seen for her fourth cycle of chemotherapy with carboplatin and paclitaxel. She reports shortness of breath and fatigue when she climbs stairs but otherwise has a good performance status. Her CBC indicates the following:

Hgb, 9.7 g/dL
Hct, 29%
MCV, 90 μm^3
Reticulocytes, 100 × $10^3/\mu L$

The peripheral smear shows normochromic and normocytic RBCs, and iron studies are within normal limits.

What is the most likely cause of P.M.'s anemia? What is the appropriate treatment?

P.M. appears to have malignancy-related anemia. Anemia occurs in up to 30% to 90% of patients with cancer.[68] The etiology is frequently complex with various attributing factors such as comorbidities, malignancy, blood loss, nutritional deficiencies, and treatment with radiation and/or chemotherapy.[68] CIA is the result of hematopoietic impairment affecting RBC production. Nephrotoxic effects of chemotherapy agents, such as platinum-containing agents, may decrease EPO production.[69] It is generally normocytic and normochromic and develops over the course of treatment. Factors that can influence the incidence of malignancy-related anemia in patients with cancer include type of malignancy and the stage and duration of disease; the type, schedule, and intensity of treatment;

and history of prior myelosuppressive chemotherapy or radiation. Cancer patients receiving chemotherapy should be routinely screened for CIA with a CBC. As per the National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology (NCCN Guidelines®), evaluation for CIA should begin at an Hgb ≤11 g/dL.[69] Additional tests, including a peripheral blood smear and reticulocyte count to detect other potential causes of anemia, should be performed.

Therapy should be directed to the underlying disease, if possible. When considering treatment options, transfusion with PRBCs should be used when rapid correction of Hgb is warranted with an expected 1 g/dL increase in Hgb and 3% increase in Hct with a single unit of PRBC. The use of transfusion for chronic management is associated with known risks, notably an increased risk of thromboembolic events in patients with cancer.[70] ESAs with or without iron supplementation should be considered for long-term management to reduce transfusion requirements. Large, randomized, multicenter trials have failed to show a clinical benefit to using ESAs in anemia that is not chemotherapy-induced. The reported increased risk of mortality and tumor progression in clinical trials of anemic patients with head and neck, breast, non-small-cell lung, lymphoid, and cervical cancers receiving ESAs resulted in a black-box warning being added to all ESA product information to advise about these and other increases in serious adverse events.[62–64] ESAs are recommended for anemic patients with cancer who are receiving myelosuppressive chemotherapy and the intent of treatment is not curative, with the possible exception of small-cell lung cancer as there are no clinical trials reporting a deleterious impact on survival.[70] As recommended by the FDA, treatment with an ESA should not be initiated unless the Hgb is <10 g/dL, and there is an additional 2 months of chemotherapy planned. The lowest dose needed to avoid RBC transfusion should be given, and use should be discontinued at the end of chemotherapy treatment.[62–64] Although response rates of 70% to 80% have been observed in clinical trials, not all patients will respond to treatment. The most common cause of nonresponse to erythropoietic therapy is absolute or functional iron

deficiency. Iron studies should be evaluated before and during therapy with supplementation given if needed; clinical trials show intravenous iron is superior when given with an ESA.[70]

In P.M.'s case, the clinician may choose from a number of anemia management options. The current course of chemotherapy can be delayed to allow for hematologic recovery and resolution of anemia symptoms. Alternatively, an RBC transfusion can be given to relieve her symptoms and allow her to better tolerate chemotherapy. Erythropoietic therapy could also be considered because the patient has metastatic disease and will continue on chemotherapy until disease progression. Treatment with an ESA dosed per Table 92-11 increases Hgb and decreases the need for blood transfusions and may be desired for P.M. Alternative dosing regimens, such as epoetin alfa 80,000 units every 2 weeks or 120,000 units every 3 weeks, or darbepoetin alfa 100 µg once weekly, 200 µg every 2 weeks, and 300 µg every 3 weeks, have proven to be safe and effective in terms of hematopoietic and transfusion effects.[70] Response of ESAs is monitored by measuring Hgb weekly until stabilization. During this time, the dose should be titrated to the lowest dose needed to avoid transfusion. A minimum of 2 weeks is required before an increase in RBCs is seen. A reduction in dose (25% for epoetin alfa and 40% for darbepoetin alfa) is required if there is >1 g/dL rise in the Hgb in any 2-week period or the Hgb reaches a level to avoid transfusion. If no response (<1 g/dL rise in Hgb and Hgb remains below 10 g/dL) is seen in 4 weeks with epoetin alfa or 6 weeks with darbepoetin alfa, a dose increase should be considered. The need for iron supplementation should also be assessed. Response should again be assessed at week 8 or 9 and appropriate dose reductions made based on Hgb level or transfusion avoidance. If no Hgb response is noted after 8 or 9 weeks of treatment or transfusions are still required, the drug should be discontinued.[62–64]

Human Immunodeficiency Virus–Related Anemia

Anemia is a common finding in patients with human immunodeficiency virus (HIV) and correlates with the severity of the disease as well as clinical outcomes.[71] In this patient population, anemia that has been identified is an independent prognostic factor for increased morbidity and mortality.[72] It has also been shown to be a marker of treatment failure in patients who do not achieve viral suppression and thus should be monitored as part of treatment.[73] Several factors may lead to the development of anemia in HIV patients, including infections, malignancies, the presence of genetic disorders of hemoglobin, nutritional deficiencies, and the use of combination antiretroviral therapy (ART). Examples of infections includes bacteria (*Mycobacterium avium* complex disease), fungus (histoplasmosis), and viruses (cytomegalovirus [CMV], herpes simplex viruses type 1 and 2, and HPV B19). The use of myelosuppressive combination antiretroviral therapy (cART) drugs such as zidovudine, zalcitabine, didanosine, lamivudine, and other medications often used to treat AIDS-associated illnesses (eg, bone marrow suppressive chemotherapy, ganciclovir, trimethoprim–sulfamethoxazole, dapsone) also contributes. Additionally, malignancies such as Kaposi sarcoma and lymphoma impair normal bone marrow function, predisposing these patients to anemia. Vitamin B_{12} deficiency is a contributing cause to anemia in up to one-third of patients and is correlated with progression to AIDS. Vitamin B_{12} malabsorption can result from HIV-infected mononuclear cells within the ileum and altered gastric mucosal functioning caused by infection.[74] Alterations in the utilization of vitamin B_{12} and folate can place a patient at risk for hematologic toxicity from drugs such as zidovudine and trimethoprim. Evidence suggests that actual virus may play a role in the pathophysiology, resulting in decreased erythropoiesis and erythropoietic response.[71] Common features of HIV-related anemia are comprised of a decreased reticulocyte count, morphologically normochromic and normocytic RBCs, adequate iron stores, and impaired response to EPO.[71]

Treatment for HIV-related anemia consists of erythropoietic therapy or removal of the offending drug, if possible. Erythropoietic

therapy has demonstrated increases in Hgb and quality of life in HIV-infected adult patients, regardless of drug therapy, $CD4^+$ count, or viral load.[71] Although no longer first-line treatment for HIV in the United States, zidovudine is still used in pregnant females and children as well as in developing countries. Its use is associated with the development of cytopenias, primarily anemia, that occur within 3 to 6 months of beginning the treatment.[75] Clinical studies show patients taking zidovudine who have baseline EPO levels <500 units/L experience a significant reduction in transfusion requirements.[76] Treatment with an ESA may be initiated in patients with zidovudine-induced anemia at 100 units/kg three times weekly. RBC indices should be closely monitored. If the Hgb exceeds 12 g/dL, then the dose should be held until it declines to <11 g/dL. At that time, a dose reduction of 25% or to the lowest dose necessary to prevent RBC transfusion is recommended. If a patient has no response after 8 weeks of therapy, the dose should be increased by 50 to 100 units/kg three times weekly at 4- to 8-week intervals or increased to 300 units/kg three times weekly. If no response is seen at a dose of 300 units/kg for 8 weeks, it is unlikely that the patient will benefit from further therapy and the drug should be discontinued.[62–64] Alternative once-weekly dosing with epoetin alfa has been evaluated at starting doses of 40,000 units.[63,64] The use of darbepoetin alfa has been assessed in patients with HIV receiving hemodialysis and is as safe and effective as epoetin alfa for treating anemia.[62]

Neoplastic Disorders and Their Treatment: General Principles

Michael Frei, Donyika Joseph, Kaiwen Wang, and Chelsea Wong

CORE PRINCIPLES		CHAPTER CASES
1	Cancer is a group of diseases characterized by uncontrolled growth and spread of abnormal cells. Tumor metastases to distant sites generally have a greater effect than the primary tumor on the frequency of complications and the patient's quality of life and mortality.	**Case 93-1 (Question 1)**
2	Avoiding known risk factors may prevent cancer. Cancer may also be prevented by appropriate use of vaccines and chemoprevention in selected groups of high-risk patients.	**Case 93-2 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
3	The histologic diagnosis of a tumor is the most important determinant of how a malignancy will be treated. The stage of cancer and the diagnosis influence the treatment and prognosis. As part of staging, diagnostic imaging facilitates identification of disease metastases.	**Case 93-3 (Question 1)**
4	The initial signs and symptoms of malignant disease are variable and depend on histology, location, and tumor size. This may influence treatment options if they affect performance status, which is a measure of a patient's functional capacity.	**Case 93-4 (Question 1)**
5	Cancer is predominately treated with three modalities: surgery, radiation, and systemic therapy. The goal of therapy should always be to cure the patient when possible.	**Case 93-5 (Question 1)**
6	Biochemical resistance to chemotherapy is the major impediment to successful treatment with most cancers. Resistance can occur de novo in cancer cells or develop during cell division as a result of mutation.	**Case 93-6 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
7	There are different types of systemic therapy: chemotherapy, targeted agents, endocrine therapy, and biologic response modifiers. Systemic therapy may be used in varying combinations and different settings. Use depends on histology, cancer stage, and the patient's predicted tolerance of the treatment.	**Case 93-7 (Question 1) Case 93-8 (Question 1) Case 93-9 (Question 1)**
8	Response to treatment is assessed by evaluating therapy's antitumor and toxic effects, including impact on the patient's overall quality of life. Evaluation should occur at scheduled intervals and include physical examination, laboratory tests, and repeat diagnostic imaging.	**Case 93-10 (Question 1)**
9	Systemic therapies used to treat cancer are potentially carcinogenic, teratogenic, or mutagenic. Handling and administering these agents poses a risk to health care workers. Appropriate policies and procedures must be in place to maximize safety and minimize risk while following national guidelines and standards.	**Case 93-11 (Questions 1–4)**

INTRODUCTION

Cancer (neoplasm, tumor, or malignancy) is not a single disease. It is a group of diseases characterized by uncontrolled growth and spread of abnormal cells. Cancer cells do not respond to the normal processes that regulate cell growth, proliferation, and survival; and they cannot carry out the physiologic functions of their normal counterparts. Other characteristics of cancer cells include their ability to invade adjacent normal tissues and break away from the primary tumor (metastasize) and travel through the blood or lymph to establish new tumors (metastases) at a distant site. Their ability to stimulate the formation of new blood vessels (angiogenesis) and their endless replication potential further contribute to their continued growth and survival.[1] Cancers can arise in any tissue in the body. If cancer cells are allowed to grow uncontrollably, they can eventually result in the death of the patient.

Cancer Statistics

Each year, the American Cancer Society (ACS) publishes an estimate for the number of new cases and number of cancer-related deaths. The National Cancer Institute publishes cancer statistics that include cancer risk, prevalence, and survival information.[2] It is estimated that 40% of men and 38% of women will eventually develop cancer and that approximately 1,918,030 new cases of cancer will be diagnosed in 2022.[3] The most common cancers and causes of cancer-related deaths in adult Americans are listed in **Table 93-1**. The incidence of cancer and cancer-related deaths can be affected by both age and ethnic background, with the incidence greater in the elderly, African American males, and Caucasian females.[3] Other factors that affect an individual's risk of developing cancer include environmental and lifestyle factors, genetic predisposition, and exposure to carcinogens.[4]

Table 93-1
Estimated Sites of New Cancer Cases and Deaths in the United States, 2022

Estimated New Cases			
Males		**Females**	
Prostate	268,490 (27%)	Breast	287,850 (31%)
Lung and bronchus	117,910 (12%)	Lung and bronchus	118,830 (13%)
Colon and rectum	80,690 (8%)	Colon and rectum	70,340 (8%)
Urinary bladder	61,700 (6%)	Uterine corpus	65,950 (7%)
Melanoma of the skin	57,180 (6%)	Melanoma of the skin	42,600 (5%)
Kidney and renal pelvis	50,290 (5%)	Non-Hodgkin lymphoma	36,350 (4%)
Non-Hodgkin lymphoma	44,120 (4%)	Thyroid	31,940 (3%)
Oral cavity and pharynx	38,700 (4%)	Pancreas	29,240 (3%)
Leukemia	35,810 (4%)	Kidney and renal pelvis	28,710 (3%)
Pancreas	32,970 (3%)	Leukemia	24,840 (3%)
All sites	**983,160 (100%)**	**All sites**	**934,870 (100%)**
Estimated Deaths			
Males		**Females**	
Lung and bronchus	68,820 (21%)	Lung and bronchus	61,360 (21%)
Prostate	34,500 (11%)	Breast	43,250 (15%)
Colon and rectum	28,400 (9%)	Colon and rectum	24,180 (8%)
Pancreas	25,970 (8%)	Pancreas	23,860 (8%)
Liver and intrahepatic bile duct	20,420 (6%)	Ovary	12,810 (4%)
Leukemia	14,020 (4%)	Uterine corpus	12,550 (4%)
Esophagus	13,250 (4%)	Liver and intrahepatic bile duct	10,100 (4%)
Urinary bladder	12,120 (4%)	Leukemia	9980 (3%)
Non-Hodgkin lymphoma	11,700 (4%)	Non-Hodgkin lymphoma	8550 (3%)
Brain and other nervous system	10,710 (3%)	Brain and other nervous system	7570 (3%)
All sites	**322,090 (100%)**	**All sites**	**287,270 (100%)**

Etiology

Cancers arise from the transformation of a single normal cell. Damage or mutation to the cell's DNA is caused by an initial "event." These events may include lifestyle, environmental, or occupational factors, as well as some medical therapies (eg, cytotoxic chemotherapy and immunosuppressive or radiation therapy) and hereditary factors. Cigarette smoking is probably the single largest factor that contributes to cancer development, responsible for ~30% of cancer deaths per year. Other preventable causes, including physical inactivity, obesity, and nutrition, are estimated to cause an

additional 30% of cancer deaths per year.[5] An estimated 2 million skin cancers diagnosed yearly are also potentially preventable with adequate skin protection.[6]

Cancer is a genetic disease. Two gene classes, oncogenes and tumor suppressor genes, are important in the pathogenesis of cancer. Damage to cellular DNA can result in mutations that lead to the development of oncogenes and loss or inactivation of tumor suppressor genes. Oncogenes are genes whose overactivity or presence in certain forms can lead to the development of cancer. Oncogenes arise from normal genes called proto-oncogenes through genetic alterations such as chromosomal translocations, deletions, insertions, and point mutations.

Growth and proliferation of normal cells are influenced by proteins, known as *growth factors*. When growth factors bind to receptors on the cell surface, they activate a series of enzymes within the cell that stimulate cell signaling pathways and gene transcription. These genes encode for proteins that regulate cell growth and proliferation. The coordination and integration of cellular signaling processes are referred to as *signal transduction*. Proto-oncogenes are responsible for encoding several components of signal transduction pathways, including growth factors, growth factor receptors, signaling enzymes, and DNA transcription factors. Abnormal forms or excessive quantities of these stimulatory proteins disrupt normal cell growth signaling pathways, leading to excessive growth and proliferation and, ultimately, a malignant transformation.

Tumor suppressor genes are normal genes that encode for proteins that suppress inappropriate cell division or growth. Gene deletions or mutations can cause these proteins to become inactivated, eliminating the normal inhibition of cell division. Alterations in a third class of genes, DNA repair genes, are also implicated in cancer. DNA repair genes encode for proteins that correct errors that may arise during DNA duplication. Mutations in these genes further contribute to the accumulation of genetic changes that promote cancer progression.

Cancer development is a multistep process. Therefore, multiple genetic mutations, including activation of oncogenes and loss or

inactivation of tumor suppressor genes within a cell, are necessary for malignant transformation.[7] Additional genetic changes are required for tumor invasion of normal tissues and metastases.

Tumor Growth

Cell Cycle

Cancer cells, similar to normal cells, proceed through a specific and orderly set of events during cellular replication referred to as the *cell cycle* (**Fig. 93-1**). The cell cycle contains four phases (M, G_1, S, and G_2), each responsible for a different task necessary for cell division. During the first activity phase, the M phase, the cell undergoes mitosis, the process of cell division. After mitosis, the cell enters the first gap or resting phase (G_1). During the G_1 resting (or gap) phase, the cell makes the enzymes necessary for DNA synthesis. The synthesis of DNA occurs during the S phase. After the S phase, the cell enters a second resting phase (G_2). RNA and other proteins are synthesized to prepare for cell division during the M phase. Cells that complete mitosis may either continue to proceed through the cell cycle to divide again, differentiate or mature into specialized cells and eventually die, or enter a third resting phase called G_0.[8]

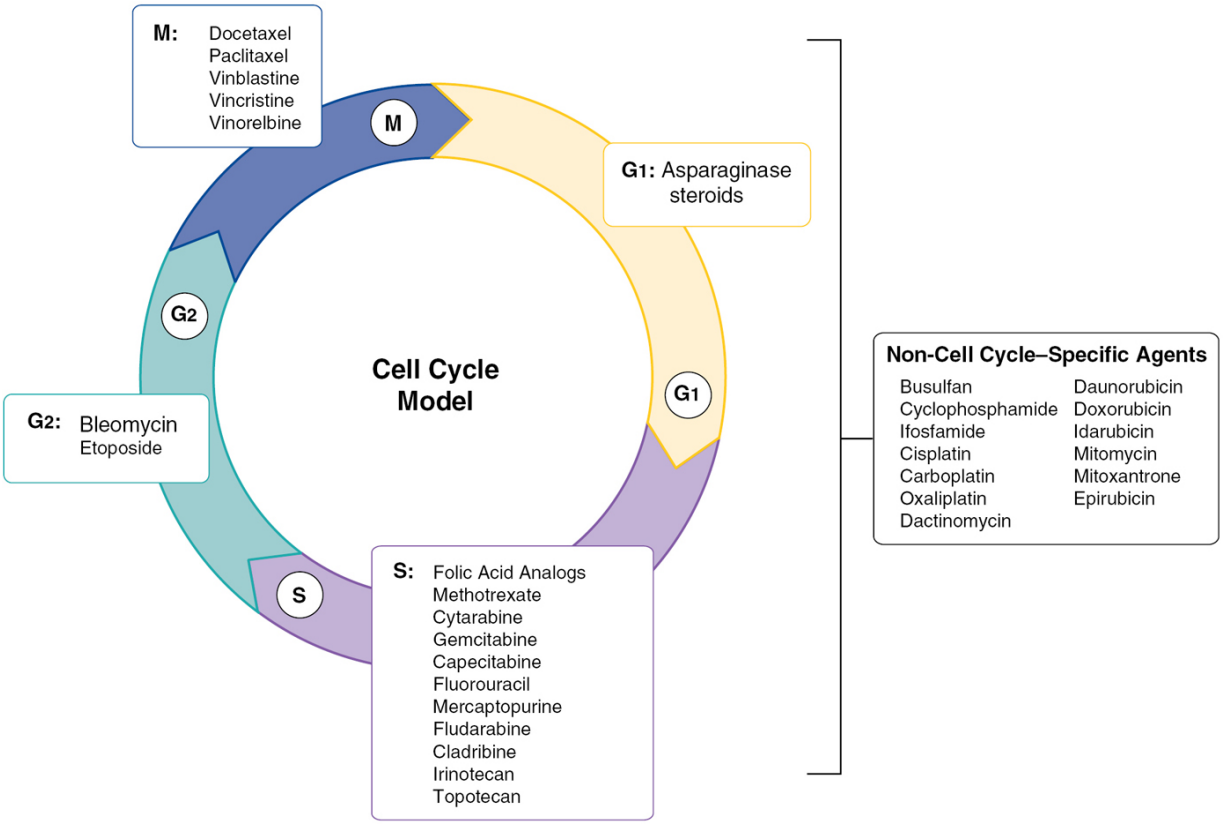

Figure 93-1 Cell cycle and effects of representative cytotoxic drugs on phases of the cell cycle.

Proliferation of normal cells is carefully controlled to balance the loss of mature functional cells with the production of new cells. As mentioned, proto-oncogenes and tumor suppressor genes provide the stimulatory and inhibitory signals, respectively, that regulate the cell cycle. The transition of cells through the cell cycle is an ordered, tightly regulated process, which involves a series of checkpoints that assess these signals and the number and integrity of the cells.[8] Cyclins, a group of interacting proteins found in the nucleus, and cyclin-dependent kinases (CDKs) make up the molecular machinery that regulates the passage of cells through various phases of the cell cycle. The cyclins combine with CDKs to form complexes that act as molecular switches. One of these molecular switches regulates whether a cell moves through a critical restriction point that occurs late in the G_1 phase to S phase. If insufficient amounts of cyclins or CDKs are present during the G_1 phase, the cell will not enter the S

phase to start cell division. Cells that pass through this restriction point are irreversibly committed to the next phase of the cell cycle.[8] A decline in the level of the CDK complex signals the end of the phase. The balance of regulation of cyclins and CDKs is influenced by several factors, including cyclin gene transcription, cyclin degradation, CDK inhibitors, and the transfer of phosphate groups to various proteins and enzymes. Activating signals from the cell's external environment are transmitted to the nucleus via growth factor receptor signaling pathways, which influence the formation of cyclins and cyclin–CDK complexes. The complexes generate phosphate groups from molecules of adenosine triphosphate (ATP) and transfer them to a protein called a *retinoblastoma protein* (pRb). If pRb acquires enough phosphate groups, it will release the transcription factors the cell needs to make proteins essential for a cell division. In other words, phosphorylated pRb promotes cell cycle progression from G_1 to S and, subsequently, cell division. Other signaling pathways inhibit cell proliferation through endogenous CDK inhibitors, which result in dephosphorylated pRb.

In cancer cells, the regulation and function of cyclins, CDK, and inhibitory proteins may be disrupted by malignant transformation, or these proteins can undergo changes that cause malignant transformation. Examples of defects in these processes include deletion of the *Rb* gene, a tumor suppressor gene that encodes for pRb, and dysregulation of the CDK through overactivation or loss of CDK inhibitors.[9] When pRb becomes inactive, excessive cell proliferation can occur. In normal cells, the *p53* gene is responsible for temporarily arresting cell growth in response to biochemical or molecular damage until the DNA damage can be repaired.[10] If the damage cannot be repaired, apoptosis (programmed cell death) occurs to prevent genetically damaged cells from growing uncontrollably. Loss or mutation of a second tumor suppressor gene, *p53*, is also common in human cancers and is associated with the resistance of cancer cells to undergo cell cycle arrest or apoptosis.

Carcinogenesis

Carcinogenesis is the process by which normal cells are transformed into cancer cells. If the balance of stimulatory and inhibitory growth signals becomes dysregulated, carcinogenesis may occur. In carcinogenesis, normal mechanisms such as apoptosis and senescence (aging) do not function properly and cannot control excessive cell division. Because abnormalities in the proto-oncogenes and tumor suppressor genes regulating these processes are present in cancer cells, the balance between cell renewal and loss of mature (senescent) cells is disrupted. Cancer cells are also less dependent on receiving stimulatory signals from external growth factors.[10] Furthermore, cancer cells possess unlimited replication potential, owing to their ability to activate telomerase.[1,11] Telomerase is an enzyme that synthesizes sequences of telomeres, thereby enabling cells to proliferate endlessly. The expression of telomerase in most normal human cells is suppressed but is reactivated in most cancer cells.[10,11] Telomeres are repeats of DNA and DNA-binding proteins that form the ends of eukaryotic chromosomes.[11] Telomere loss occurs with each successive cell replication, and after a critical length is reached, the cell undergoes irreversible growth arrest (replicative senescence).[11] Unlike normal cells, in which a finite telomere sequence regulates their life span, cancer cells are capable of immortality through their ability to maintain their telomeres indefinitely.

Metastasis

CASE 93-1

Question 1: S.T., a 16-year-old boy, presented to the emergency department with a painful, swollen right leg. X-ray examination confirmed a fracture that appeared to be caused by a tumor mass in the bone. Biopsy of the bone mass confirmed osteogenic sarcoma. A chest x-ray study showed three nodules that were also believed to be malignant tumors.

Does S.T. also have lung cancer or are the tumors in S.T.'s lungs metastases from the sarcoma in his leg?

S.T. does not have lung cancer. Tumor nodules in his lung are most likely metastases from the sarcoma in his leg. The ability of cancer cells to disseminate and form metastases represents their most malignant characteristic. Tumor metastases to distant sites generally have a greater effect than does the primary tumor on the frequency of complications and patient's quality of life. Metastases also have a greater impact than does the primary tumor on mortality, with metastases associated with most cancer-related deaths. Consequently, individuals diagnosed with metastases face a worse prognosis.

Cancer cells must develop new blood vessels to obtain nutrients and spread to distant sites (metastasize). In response to low oxygen supply (hypoxia) and other factors, cancer cells and surrounding tissues secrete growth factors that stimulate the growth of new blood vessels (angiogenesis) from existing blood vessels in surrounding normal host tissue. Vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and basic fibroblast growth factor (bFGF) are growth factors needed for sustained endothelial cell growth. Once released by tumor cells, these growth factors bind to tyrosine kinase receptors on the surface of endothelial cells of existing blood vessels and activate a series of intracellular relay proteins that transmit signals to genes in the nucleus to produce factors required for new endothelial cell growth.[12] Once older endothelial cells become activated by growth factors, they begin making matrix metalloproteinase (MMP) enzymes. These enzymes destroy the extracellular matrix of surrounding cells, allowing older endothelial cells to invade the extracellular matrix and begin cell division.[12] This process of invasion and proliferation is repeated several times until new blood vessels are formed.

Tumor cells can use these newly formed blood vessels to facilitate their spread to distant locations. Cells must break away from the primary tumor and travel to other sites in the body to form metastases. Normally, cells adhere to one another and the extracellular matrix. The cell-to-cell adhesion molecules are called *cadherins*, and the cell-to-extracellular matrix molecules are called

integrins. In cancer cells, these molecules are often absent, allowing tumor cells to easily move away from the primary tumor mass.

Once a tumor cell leaves the primary mass, it travels through the blood vessels and lymphatic system within the body to form metastatic site(s). Usually, tumor cells spread to the first capillary bed they encounter after their release from the primary tumor. If the primary site drains its blood supply into the vena cava, the cancer cells will reach the capillary bed in the lung. Similarly, if the primary site drains its blood supply into the portal circulation, the cancer cells will reach the capillary bed in the liver. In addition, cancer cells can potentially pass through the first capillary bed they encounter and enter the arterial circulation where they can distribute to other organs and tissues throughout the body.

Growth conditions (eg, growth factors and physiologic conditions) within a tissue or organ also can determine the location of a metastatic site. After a cancer cell establishes a metastatic site, it must again undergo angiogenesis to ensure continued growth. Together, angiogenesis and hematogenous or lymphatic spread help cancer cells invade healthy tissues and increase morbidity and mortality associated with the disease.

Prevention of Cancer

Tobacco

Cigarette smoking is probably the single largest factor that contributes to cancer development, increasing the risk of multiple cancer types including lung, head and neck, gastrointestinal, bladder, and cervical cancers.[5] Therefore, tobacco cessation and abstinence play an important role in the prevention of cancer. For more information, visit the following page on the ACS website: https://www.cancer.org/cancer/cancer-causes/tobacco-and-cancer.html. For a review of tobacco dependence and methods for cessation, see Chapter 91, Tobacco Use and Dependence.

CHEMOPREVENTION

Chemoprevention is the use of a drug or substance to reverse, inhibit, or prevent the development of cancer. Use of chemoprevention is helpful in selected groups of high-risk patients with breast, colorectal, and prostate cancers.[13] For a discussion of chemoprevention for these cancers, see Chapter 97, Breast Cancer, Chapter 99, Colorectal Cancer, and Chapter 100, Prostate Cancer.

HUMAN PAPILLOMA VIRUS VACCINES

CASE 93-2

QUESTION 1: M.M., a 44-year-old female, asks you about vaccines to prevent cervical cancer.

Should M.M. consider vaccination for her daughter or her son? Would this substitute for Papanicolaou (Pap) smear screening for her daughter?

The human papillomavirus (HPV) is primarily transmitted through sexual contact; serotypes 16 and 18 (HPV-16, 18) cause ~70% of cervical cancers.[14] There is only one HPV vaccination being distributed in the United States, HPV 9-valent vaccine (Gardasil® 9), which is administered over the course of 6 months. The vaccine protects against HPV strains 6, 11, 16, 18, 31, 33, 45, 52, and 58. The vaccine has demonstrated efficacy in reducing the incidence of cervical intraepithelial neoplasia (CIN), a premalignant lesion that can lead to cervical cancer.[15,16] Because the progression of HPV infection to invasive cervical cancer requires several years to possibly decades, CIN is utilized as a surrogate efficacy end point in HPV vaccine clinical trials. It is anticipated that the use of HPV vaccines will ultimately lead to a reduction in the incidence of cervical cancer.

Gardasil® 9 is also approved for the prevention of vulvar intraepithelial neoplasia (VIN) and vaginal intraepithelial neoplasia (VAIN) in females, as well as prevention of HPV-related genital warts and anal cancer in males. However, there are no data to support the use of these vaccines to prevent other cancers associated with HPV, such as penile cancer or head and neck cancers.[16]

Routine Pap smear and HPV screening should continue for vaccinated females because the vaccines do not prevent all oncogenic types of HPV. The duration of vaccine-induced anti-HPV immunity is also unknown.

M.M. should consider HPV vaccination for her daughter. The vaccine is indicated in females of ages 9 to 45 years, but the vaccines are most effective if initiated before sexual activity. Whether or not M.M.'s daughter is vaccinated, she should still receive routine Pap smear screening according to current guidelines.[17] The HPV 9-valent vaccine is approved in males ages 9 to 45 years; therefore, M.M. should also consider vaccination for her son. The Centers for Disease Control recommends HPV vaccination for all females and males at the age of 11 to 12 years.[18]

DIET

Diet has been linked to the development of colon and breast cancers. The ACS advocates a healthy diet that consists of vegetables, fruit, whole grains, and fiber and is low in fat and red meat.[19] For more information, visit the following page on the ACS website: https://www.cancer.org/healthy/eat-healthy-get-active/acs-guidelines-nutrition-physical-activity-cancer-prevention/guidelines.html.

Migrant studies suggest that diet, environmental, or social factors play a role in the development of prostate cancer and that the incidence of colon cancer in a population increases as individuals migrate from a low-incidence region to a high-incidence region.[20,21] In females, the risk of breast cancer is increased with obesity, but an association with a high-fat diet is less clear.[22] Moderate alcohol consumption has also been associated with an increased risk of breast cancer.[23]

SUN AND ULTRAVIOLET RADIATION EXPOSURE

Most risk factors associated with skin cancer are uncontrollable, with the exception of sun exposure and other forms of ultraviolet (UV) radiation. The interaction between UV radiation and skin cancers is

complex because nonmelanomas (eg, basal cell and squamous cell carcinomas) are associated with cumulative UV radiation exposure, and certain cutaneous melanomas are associated with excessive, intermittent UV radiation exposure.[24] The risk of melanoma is further increased in people who have a history of five or more severe sunburns in their lifetime, particularly during adolescence, or history of tanning bed use.[24,25] Depletion of the ozone layer in the stratosphere may also contribute to the increased incidence of melanoma.[24]

Prevention of skin cancer is based on limiting sun and UV radiation exposure. The ACS guidelines recommend avoiding or limiting sun exposure from 10:00 AM to 4:00 PM when the UV rays are the strongest and avoiding tanning bed or sun lamp use. Protective clothing (hat, sunglasses, long-sleeved shirt, and pants) and sunscreen are also advised to minimize exposure.[25] However, the protective effects of sunscreen alone against melanoma, particularly for intentional sun exposure, are controversial and should not be used to prolong time in the sun.[25,26]

Screening and Early Detection of Cancer

Standardized screening tests help identify disease in asymptomatic individuals (screening) or diagnose disease in symptomatic individuals (early detection). The cancer screening tests recommended by the ACS meet four basic requirements: (a) there must be good evidence that the test is effective in reducing morbidity or mortality; (b) benefits of the test should outweigh its risks; (c) costs of the test should be in balance with its presumed benefits; and (d) the test should be practical and feasible within the existing health care setting. For more information, visit the following page on the ACS website: http://www.cancer.org/Healthy/FindCancerEarly/CancerScreeningGuidelines/american-cancer-society-guidelines-for-the-early-detection-of-cancer.

Screening guidelines are updated frequently, and newest guidelines should be consulted when counseling patients. Professional organizations including the ACS (http://www.cancer.org) and National Comprehensive Cancer Network (NCCN; http://www.nccn.org) regularly publish recommendations for screening of breast, cervical, colon, lung, and prostate cancers.[27]

Diagnosis and Staging of Cancer

The histologic diagnosis of a tumor is the most important determinant of treatment selection. This is because its histologic classification influences its natural history, pattern of progression, and responsiveness to treatment. A biopsy followed by a microscopic and biochemical evaluation by a pathologist can provide the most accurate histologic diagnosis. Thereafter, staging can begin.

CASE 93-3

QUESTION 1: J.S. is diagnosed with lung cancer after a biopsy of a large lung mass. Chemotherapy, radiation, and surgery are commonly used to treat patients diagnosed with lung cancer.

What information is needed to select a treatment plan for J.S.?

The stage of the cancer, as well as the histologic diagnosis, influences both the treatment selection and prognosis. Staging is the process that determines the extent or spread of the disease.

Determining the stage of the cancer typically requires tests that can physically or radiographically measure the size of the primary tumor and assess for evidence of tumor spread (eg, radiographs, computed tomography [CT] scans, magnetic resonance imaging [MRI] scans, or positron emission tomography [PET] scans) and pathologically examine regional lymph nodes.[28] Clinicians also evaluate symptoms (eg, pain) or signs (eg, swelling and abnormal laboratory findings) that may indicate tumor involvement at a distant site. Common sites of tumor metastases are shown in **Table 93-2**.

Table 93-2

Common Sites of Metastases for Selected Tumors

Cancer Type	Common Sites of Metastases
Breast	Bone (osteolytic lesions), lung, liver, and brain
Lung	Liver, brain, adrenals, pancreas, contralateral lung, and bone
Prostate	Bone (osteoblastic lesions), liver, and lung
Colon	Liver, peritoneal cavity, and lung
Ovarian	Local spread in the peritoneal cavity

Staging schemas have been developed for all major types of cancers. For solid tumors, the most widely used and accepted staging classification is the TNM system, which incorporates the size of the primary tumor (T), the extent of regional lymph node spread (N), and the presence or absence of metastatic spread to distant organs (M). Within each TNM category, the extent of cancer involvement is related to prognosis. Most solid tumor staging systems also incorporate the TNM classification into broader groups, called *stages*, to facilitate treatment decisions and determine goals of care among patient populations. Classification of stages differs among solid tumor types. Refer to the chapters on malignancy-specific classification for TNM staging of breast, lung, prostate, and colorectal cancers.

Although the TNM system enables staging of solid tumors, it does not enable staging for hematologic malignancies, including leukemias, lymphomas, and multiple myeloma. Because hematologic malignancies occur in the blood cells and lymphatic tissues that are widely distributed throughout the body, the TNM staging system cannot sufficiently describe these diseases. To define the extent of disease, guide treatment, and provide prognostic information, specific staging systems have been developed for various hematologic malignancies. Staging systems for hematologic malignancies are discussed in further detail in Chapter 96, Adult Hematologic Malignancies.

Staging systems for some tumors also include other characteristics to further determine the stage and prognosis of the disease, such as clinical signs and symptoms, biochemical

characteristics of the tumor including mutation analysis, genetic mutations of the patient, or other laboratory tests. Tumor staging is done at the time of initial diagnosis and periodically during treatment to assess the patient's response to therapy. Staging should also be repeated (a) when evidence shows that the cancer has progressed during treatment or recurred after therapy to establish the most appropriate next-line therapy, and (b) to enable measurement of response to that therapy.

J.S. needs to undergo the appropriate imaging scans, laboratory studies, and clinical evaluation so that her lung cancer can be staged. These tests may include blood tests (eg, complete blood cell and platelet count, and liver function tests), determination of tumor biochemical characteristics, brain MRI, bronchoscopy, and PET. Once staging is completed, treatment recommendations and options can then be determined. Treatment options for lung cancer based on stage are further discussed in Chapter 98, Lung Cancer.

CLINICAL PRESENTATION AND COMPLICATIONS OF MALIGNANCY

The initial signs and symptoms of malignant disease can vary and predominantly depend on histologic diagnosis, location (including metastases), and size of the tumor. Pain secondary to compression, obstruction, and destruction of adjacent tissues and organs is the most common presenting symptom. Other common initial symptoms reported by patients with cancer include anorexia, weight loss, and fatigue. Certain symptoms, however, may be obscured by a concomitant illness, such as chronic lung disease in patients with lung cancer. In addition, tumor involvement of the liver, kidneys, or lungs and/or compression or obstruction of liver, kidney and other abdominal organs can complicate therapy by causing significant organ dysfunction and metabolic disturbances. Life-threatening complications that require immediate intervention include obstruction of the superior vena cava, spinal cord compression, and brain metastases.

CASE 93-4

QUESTION 1: P.N., a 59-year-old female, presents with shortness of breath, fatigue, anorexia, weight loss, and abdominal pain and distension that have worsened significantly during the previous 3 weeks. A CT scan of her abdomen shows a large mass surrounding the head of her pancreas with biopsy results that confirm pancreatic adenocarcinoma. The staging workup confirms the presence of distant metastases. Her husband states that she was previously an active person, but that she most recently has been unable to dress herself or participate in normal daily activities. He states that she spends most of the day in bed.

Will her activity level influence the type of treatment that she can receive?

Cancer can have a profound effect on a patient's quality of life and their ability to tolerate appropriate therapy. Patients with malnutrition secondary to anorexia, mechanical obstruction, or pain may not tolerate some therapies because of significant physical debility. Performance status is a measure of functional capacity and reflects a patient's ability to ambulate, care for themselves, and carry out normal activities. For several cancers, poor pretreatment performance status is associated with decreased ability to tolerate treatment, decreased tumor response to treatment, and worsened clinical outcome. In these cases, especially if the cancer is not known to respond well to treatment, a less aggressive treatment regimen may be recommended. For this reason, performance status is important to assess at the time of staging evaluation and periodically during treatment. Different scales (ie, Karnofsky score, Eastern Cooperative Oncology Group [ECOG]) can be used to determine performance status. The Karnofsky and ECOG performance scales are depicted in **Table 93-3**.[29] Because P.N. has a poor performance status and may not tolerate chemotherapy well, her oncologist may recommend a less toxic treatment plan. Because other conditions, such as depression, could contribute to her symptoms, P.N. should undergo comprehensive evaluation.

Table 93-3
Performance Status Scales

Eastern Cooperative Group		Karnofsky	
Grade	**Description**	**Grade**	**Description**
0	Fully active, able to carry on all predisease performance without restriction	100	Able to carry on normal activity; no evidence of disease
		90	Able to carry on normal activity; minor signs or symptoms of disease
1	Restricted in physically strenuous activity, but ambulatory and able to carry out work of a light or sedentary nature	80	Normal activity with effort, some signs of symptoms of disease
		70	Cares for self, but unable to carry on normal activity or do active work
2	Ambulatory and capable of all self-care, but unable to carry out any work activities. Up and about >50% of waking hours	60	Requires occasional assistance, but is able to care for most of personal needs
		50	Requires considerable assistance and frequent medical care
3	Capable of only limited self-care, confined to bed or chair >50% of waking hours	40	Disabled; requires special care and assistance
		30	Severely disabled; hospitalization is indicated, although death not imminent
4	Completely disabled; cannot carry on any self-care; totally confined to bed or chair	20	Very ill; hospitalization and active supportive care necessary
		10	Moribund
5	Dead	0	Dead

TREATMENT

CASE 93-5

QUESTION 1: T.J., a 40-year-old male with no significant medical history, presents to his physician with abdominal pain, nausea and vomiting, weakness, and weight loss. On physical examination, he is noted to be slightly jaundiced. A CT scan of his abdomen reveals a mass present in the peripancreatic area that is suggestive of malignancy.

Once diagnosed and staged, how will T.J.'s malignancy be treated and what is the goal of therapy?

The choice of specific therapy and its goals depends not only on the type, histology, and stage of the cancer but also on the patient's predicted tolerance of the side effects of the various treatment options. The goal of therapy should always be to cure the patient when possible. The likelihood of cure is greater when the tumor burden is low (ie, lower stage). If cure is not possible, therapy

becomes palliative in nature, with disease control and symptom management the priority. Goals of therapy should be balanced so that quantity and quality of life are both adequately considered.

Cancer is predominately treated with three modalities: surgery, radiation, and systemic therapy (including chemotherapy, targeted therapy, biologic agents, etc.). Systemic therapy is the primary treatment modality for hematologic malignancies. In most solid tumor malignancies, early-stage and localized disease is treated with surgery, radiation therapy, or, in some cases, both. For advanced disease (presence of metastases or recurrence after initial therapy), solid tumor malignancies are usually treated with systemic therapy as the primary treatment modality. T.J.'s treatment will be dependent on tumor histology, stage, and expected prognosis. If T.J. has potentially curable disease, he should be treated with curative intent therapy, whereas if T.J. has advanced disease that denotes a poor prognosis, he should be treated with palliative therapy.

Surgery

Surgery is an important treatment option for patients diagnosed with certain solid tumors. With the recent advances in surgical techniques (eg, minimally invasive procedures) and improved understanding of patterns of tumor growth and spread, successful resections are possible for an increasing number of patients. Surgery may be used as preventive therapy (eg, removal of colonic polyps or cervical dysplasia), diagnostic treatment, or staging of some cancers.

Surgery can be used to manage both localized and advanced tumors. When surgery provides curative therapy for a localized tumor, the surgeon removes the tumor plus a margin of normal tissue surrounding the tumor. For extensive, localized tumors that cannot be completely removed, selected patients may undergo cytoreductive surgery to partially resect the tumor to improve the likelihood that subsequent chemotherapy or radiation therapy may successfully kill the tumor.

Patients with metastatic disease may have palliative surgery to relieve pain or improve functional abnormalities caused by the advanced tumor (eg, gastrointestinal obstruction). Palliative surgery may improve quality of life but may not prolong survival.

Radiation

Radiation may be administered as either curative or palliative therapy for solid tumors. Radiation is administered in varying doses depending on the type of tissue being treated (eg, bone, lung, breast, liver, or brain) and the intent of therapy (palliative or curative). A limit exists to the total amount of radiation that can be delivered to the area being treated depending on the type of tissue. Damaging effects of radiation on the normal tissues surrounding the tumor can be acute and chronic, such as inflammation and subsequent fibrosis of the radiated field. Certain side effects may be exacerbated if given concomitantly with chemotherapy. For example, chemotherapy administered at the completion of radiation can produce “radiation recall,” a local toxicity that manifests as skin redness, swelling, and peeling at the radiation site.

Not all cancers are sensitive to radiation, so there is limited application in these cases. For radiation-sensitive tumors (**Table 93-4**), potential advantages exist over surgery. Radiation therapy can be given to multiple sites simultaneously. It may encompass a wider area around the tumor and treat tumors in regions of the body where surgery cannot safely be performed or in cases when surgery could result in considerable disability or disfigurement.

Table 93-4

Cancers Frequently Treated With Radiation Therapy

Acute lymphocytic leukemia (central nervous system radiation)
Brain and central nervous system
Breast
Head and neck cancers, squamous cell
Lung
Lymphomas

Neuroblastoma
Prostate
Rectal
Testicular, seminoma

Multiple methods are used to administer radiation to tumors. External-beam radiotherapy and brachytherapy are two types that are commonly used. Newer radiation therapy techniques, including intraoperative radiation, hyperfractionated radiation, stereotactic radiosurgery, intensity-modulated radiation therapy, charged-particle (proton) radiation therapy, and computerized three-dimensional conformal treatment planning, may reduce associated toxicities, enhance tumor responsiveness, and improve the clinical usefulness of radiation.[30-32]

Systemic Therapy

Not all cancers can be treated by surgery or radiation therapy. Patients may present with widespread metastatic disease at diagnosis or recur following primary treatment with surgery or radiation. Patients may also have residual tumor following initial surgery or radiation, requiring additional treatment. In these circumstances, systemic treatments including chemotherapy, targeted therapy, endocrine therapy, and biologic response modifiers generally offer the only hope of controlling disease.

CHEMOTHERAPY

The National Cancer Institute defines chemotherapy as drugs that stop the growth of cancer.[33] For the purposes of this chapter, chemotherapy will be defined as cytotoxic therapy that is directed toward rapidly dividing cells. Chemotherapy kills cancer cells by damaging DNA, interfering with DNA synthesis, or inhibiting cell division. Chemotherapy agents are classified by their effect on the cell cycle or mechanism of action. Agents that affect a specific phase of the cell cycle are referred to as *phase-specific agents* or *schedule-dependent agents*. In contrast, agents that affect any phase of the

cell cycle are referred to as *phase-nonspecific agents* or *dose-dependent agents* (see Fig. 93-1). The specific mechanisms of action for several chemotherapy agents are described in **Table 93-5**.[34]

Table 93-5
Chemotherapy Agents

Subclass	Agent	Mechanism of Action	Notable Toxicities
Alkylating Agents			
Nitrogen mustards	Bendamustine Chlorambucil Cyclophosphamide Ifosfamide Melphalan Thiotepa	Cross-links DNA strands, leading to cell death	Myelosuppression; nausea, vomiting; fatigue
Nitrosoureas	Carmustine Lomustine	Interferes with normal cellular function via cross-linking of DNA and RNA strands	Myelosuppression; nausea, vomiting; pulmonary toxicity; hepatic and renal dysfunction
Platinum analogs	Carboplatin Cisplatin Oxaliplatin	Reacts with nucleophilic sites on DNA forming cross-links	Myelosuppression; nausea, vomiting; peripheral neuropathy; delayed hypersensitivity reactions; secondary malignancy
Triazenes	Dacarbazine Temozolomide	Alkylates DNA, leading to double-strand breaks and cell death	Myelosuppression; nausea, vomiting, anorexia; fatigue; headache; alopecia
Antimetabolites			
DNA demethylation agents	Azacitidine Decitabine Nelarabine	Incorporates into RNA and DNA and inhibits methylation	Myelosuppression; nausea, vomiting, diarrhea; bruising, petechiae; fatigue, fever
Folic acid antagonists	Methotrexate Pemetrexed Pralatrexate	Inhibits dihydrofolate reductase; interferes with DNA synthesis, repair, and cellular replication	Myelosuppression; stomatitis; nausea; fatigue; hepatic dysfunction
Purine analogs	Cladribine Clofarabine Fludarabine Mercaptopurine Thioguanine	Inhibits DNA synthesis and repair by incorporating into DNA	Myelosuppression; nausea, vomiting, anorexia; fatigue

Pyrimidine analogs	Capecitabine Cytarabine Fluorouracil Gemcitabine	Incorporates into RNA and DNA; interferes with RNA function	Myelosuppression; nausea, vomiting, stomatitis, diarrhea
Antimitotic Agents			
Epothilones	Ixabepilone	Binds directly to β-tubulin; promotes stabilization of microtubules	Alopecia; myelosuppression; peripheral neuropathy; arthralgia, myalgia; stomatitis, nausea, vomiting, diarrhea
Taxanes	Cabazitaxel Docetaxel Paclitaxel Paclitaxel, albumin-bound	Binds to β-tubulin; promotes stabilization and suppresses disassembly of microtubules	Myelosuppression; alopecia; nausea, vomiting, diarrhea; peripheral neuropathy; myalgia, arthralgia; fatigue
Vinca alkaloids	Vinblastine Vincristine Vinorelbine	Binds to tubulin, interfering with microtubule assembly and mitotic spindle formation	Myelosuppression; constipation; bone pain; neurotoxicity, neuropathies; vesicant
Antitumor Antibiotics			
Anthracyclines	Daunorubicin Doxorubicin Doxorubicin, liposomal Epirubicin Idarubicin Valrubicin	Stabilizes the cleavable complex between topoisomerase II and DNA, causing single- and double-strand DNA breaks	Myelosuppression; mucositis; alopecia; nausea, vomiting; cumulative cardiac toxicity; secondary malignancy
DNA topoisomerase inhibitors	Etoposide Irinotecan Topotecan	Inhibits topoisomerases, leading to DNA strand breaks	Myelosuppression, fatigue; alopecia
Other Alkylating Agents			
Other agents	Lurbinectedin Trabectedin	Covalently binds to minor DNA groove, altering transcription	Myelosuppression; nausea, vomiting; hepatotoxicity

DNA, deoxyribonucleic acid; RNA, ribonucleic acid.

Factors that influence response to chemotherapy

Cell Kill

Studies using rodent animal models during the 1960s demonstrated that the number of tumor cells killed by chemotherapy is proportional to the dose when the growth fraction is 100% (ie, all cells are dividing) and the tumor cells are sensitive to the agent.[35,36] For example, if a dose of chemotherapy reduces the tumor burden from 10^{10} to 10^{8} cells, the same dose administered when only 10^{7} cells are present should reduce the tumor burden to 10^{5} cells. This theory has become known as the *cell-kill* or *log-kill hypothesis* (**Fig. 93-2**).

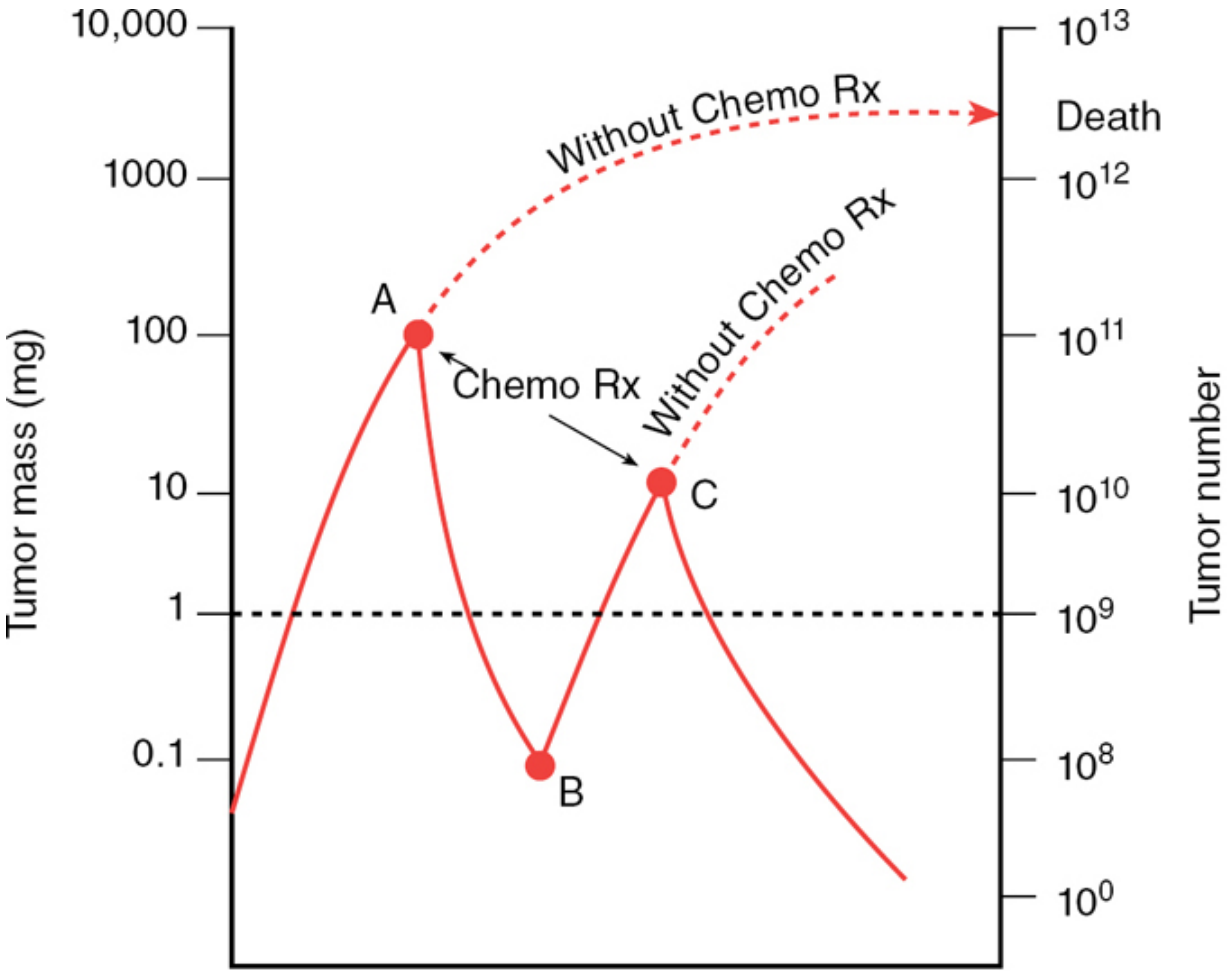

Figure 93-2 Log-kill hypothesis. The growth rate of a tumor is initially very rapid and eventually slows as it approaches 10^{11} cells. Two trillion (2×10^{12}) cells or 2 kg of tumor is lethal to humans. An effective chemotherapy treatment (Chemo Rx) given at point A will decrease the tumor number to point B. Regrowth of the tumor will occur during the recovery period until further chemotherapy is given at point C.

In the clinical setting, tumor cells do not always decrease predictably with each successive course of chemotherapy. This is because the growth fraction of human tumors is not 100% and the cell population is heterogeneous, with some cells that are resistant to chemotherapy.

Dose Intensity

Dose intensity is defined as the chemotherapy dose per unit time during which treatment is given (eg, milligrams/meter squared/week). Drug resistance might be overcome by increasing the dose of chemotherapy. Evidence suggests that reducing a dose can cause treatment failure in patients with chemotherapy-sensitive tumors who are receiving their first chemotherapy treatment.[37] A direct relationship between dose intensity and response rate has been reported in several tumor types including breast cancer, lymphomas, ovarian cancer, and small cell lung cancer.[38,39] However, dose-intensive therapy has not consistently improved the overall cure rate of most solid tumors.

The dose intensity for most chemotherapy regimens is limited by the major dose-related toxicity, bone marrow suppression. To minimize this toxicity and administer higher doses, patients may receive hematopoietic growth factors, autologous stem cell transplantation, or altered schedules of drug delivery.[40,41]

Schedule Dependency

Chemotherapy is administered in cycles (eg, every 2, 3, or 4 weeks) with recovery periods between cycles. A typical course of chemotherapy usually consists of several cycles. The interval of time between cycles depends on the cancer diagnosis and the agents being used. The optimal schedule is influenced by the pharmacokinetics of the agent. For example, phase-specific agents exert their cytotoxic effects only when the cell is in a particular phase of the cell cycle. If a phase-specific agent with a short half-life is administered by intravenous bolus, a significant number of tumor cells may not be in the vulnerable phase of the cell cycle during exposure to the agent. Comparatively, the same agent administered by frequent intravenous bolus or continuous infusion could expose more cells to the agent during the vulnerable phase.[42]

Drug Resistance

CASE 93-6

QUESTION 1: B.C. is a 39-year-old male with aggressive non-Hodgkin lymphoma (NHL). At the time of diagnosis, B.C. had enlarged cervical lymph nodes, dyspnea, and a large mediastinal mass noted on chest x-ray examination. Chemotherapy was initiated with rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (RCHOP). After the first cycle of chemotherapy, B.C.'s lymphadenopathy was greatly reduced. After cycle 2, a repeat chest x-ray showed marked improvement. When he returned for his fifth cycle of chemotherapy, recurrent lymphadenopathy was noted, and the chest radiograph confirmed enlargement of the mediastinal mass.

Why is B.C.'s cancer growing despite continued chemotherapy, and how should his treatment be altered?

Most likely, B.C.'s cancer is now growing because the tumor has become resistant to the chemotherapy. Therefore, it would be wise to discontinue the current regimen. Biochemical resistance to chemotherapy is the major impediment to successful treatment with most cancers.[37] Resistance can occur de novo in cancer cells or develop during cell division as a result of mutation.[37] In 1979, a proposed mathematical model known as the Goldie–Coldman hypothesis predicted that tumor cells mutate at a rate related to the genetic instability of the tumor.[43] Thus, the probability that a tumor mass will contain resistant clones is related to both the rate of mutation and the size of the tumor. Many mechanisms have been identified by which cancer cells resist the activity of cytotoxic agents.

Some cell lines that become resistant to a single chemotherapy agent may also be resistant to structurally unrelated cytotoxic compounds. This phenomenon is called *pleiotropic drug resistance* or *multidrug resistance* (MDR).[44] Cell lines that display this type of resistance are generally resistant to natural product cytotoxic agents such as the vinca alkaloids, antitumor antibiotics, epipodophyllotoxins, camptothecins, and taxanes. The primary mechanism believed to be responsible for MDR is an increase in efflux transporters such as P-glycoprotein in the cell membrane. These proteins mediate efflux of the chemotherapy agent, causing decreased accumulation of drug within the cell and decreased cytotoxicity.[44] Other transport proteins (eg, breast cancer resistance

protein [BCRP]) have been implicated in resistance to chemotherapy as well.[45]

Another type of MDR is caused by changes or mutations of drug targets, for example, the altered binding of topoisomerase II, an enzyme that promotes DNA strand breaks in the presence of anthracyclines and epipodophyllotoxins.[46] Because of the likelihood of MDR, B.C. should receive a chemotherapy regimen that does not include agents transported from tumor cells by the MDR mechanism. An alternative regimen such as gemcitabine or oxaliplatin, with or without rituximab, may be a reasonable option because this regimen is active against NHL, and these drugs are not known substrates for various efflux transporters.

Tumor Site

The cytotoxic effects of chemotherapy agents are related to the time the tumor is exposed to an effective concentration of the agent (ie, concentration × time [C × T]). The drug dose, infusion rate, route of administration, lipophilicity, and protein binding can influence the concentration–time product. Other factors, such as tumor size and location, can also critically affect an agent's cytotoxicity. As tumors grow larger, their degree of vascularity lessens, making it more difficult for agents to penetrate the entire tumor mass. Tumors located in sites of the body with poor drug penetration (eg, the brain) may not receive a sufficient concentration to provide effective kill.

Pharmacogenetics

Antitumor activity and adverse effects of chemotherapy agents are associated with the presence of genetic polymorphisms that can affect the metabolism and disposition of drug. See Chapter 97, Breast Cancer, and Chapter 99, Colorectal Cancer, for a more detailed discussion of genetic polymorphisms associated with UDP glucuronosyltransferase 1A1 (UGT1A1), cytochrome P450 2D6 (CYP2D6), and human epidermal growth factor receptor 2 (HER2) receptor positivity.

Combination chemotherapy

CASE 93-7

QUESTION 1: K.K. has newly diagnosed stage II, bulky Hodgkin lymphoma. She initially presented with asymptomatic lymphadenopathy, night sweats, and a 15% weight loss in the previous 2 months. K.K. is to begin chemotherapy today with doxorubicin, bleomycin, vinblastine, and dacarbazine. All four agents have activity in Hodgkin lymphoma.

Why is it recommended that K.K. receive all four drugs, rather than just one drug?

Although single-agent chemotherapy can cause significant early regression of Hodgkin lymphoma, acute lymphocytic leukemia, and adult NHL, some tumors show only a partial, very short response to single-agent therapy. In Hodgkin lymphoma, the use of combination chemotherapy results in long-term, disease-free survival for >60% of patients. If K.K. were to receive single-agent therapy, her disease would not be cured. Combination chemotherapy is recommended to provide her with the best chance for long-term, disease-free survival.

Combination chemotherapy provides broader coverage against resistant cell lines within the heterogeneous tumor mass. Several principles provide the basis for selecting the agents to be included in a chemotherapy regimen:

- Agents with demonstrable single-agent activity against the specific type of tumor should be used in combination therapy.
- Agents in the regimen should have different mechanisms of action.
- Agents should not have overlapping toxicities so that the severity and duration of acute and chronic toxicities are minimized.
- Agents in the regimen should be used in their optimal dose and schedule.

Subsequent chapters provide examples of commonly used systemic regimens in the treatment of hematologic and solid tumor malignancies.

Primary treatment is the first-line therapy a patient receives, and in some tumor types it is referred to as *induction therapy*. Choice of primary treatment is governed by observations made from clinical trials that demonstrate a given regimen has high activity against the tumor. These regimens may include chemotherapy, targeted agents, endocrine agents, or biologic agents. After primary therapy, patients may receive additional treatment in an attempt to further eradicate residual disease and improve their chances for long-term survival. This treatment may be termed *consolidation*, *intensification*, or *maintenance* therapy (see subsequent chapters for specific discussion of these agents). Second-line treatment is administered after the tumor has become refractory to primary therapy or if the patient is unable to tolerate first-line therapy. Table 93-5 lists examples of commonly used agents.

Adjuvant therapy

CASE 93-8

QUESTION 1: F.R. is a 58-year-old female with no significant past medical history who recently underwent surgical resection for her stage III ovarian cancer. She has been told that she currently has no evidence of disease; however, she is also told that she should now receive six cycles of combination chemotherapy.

Why would chemotherapy be recommended now when she has no detectable disease?

Micrometastases or residual disease may still be present in some patients after completion of primary treatment. These patients have a high probability of disease recurrence, even though the primary treatment may have successfully removed all visual evidence of the primary tumor. To eradicate any undetectable tumor, systemic therapy may be recommended after initial curative surgery (or radiation therapy). Systemic treatment administered after primary therapy is referred to as *adjuvant therapy*. (In the case of F.R., primary therapy was surgery, and chemotherapy would be

considered adjuvant therapy.) Because the tumor burden is relatively low at this time, adjuvant therapy should immediately follow primary therapy. For adjuvant therapy to provide benefit, the risk of tumor recurrence must be high and effective agents must be available to eradicate the tumor. Adjuvant therapy is considered standard of care for some stages of breast, lung, and colorectal cancer, but it has also benefited select patients with ovarian cancer, Ewing sarcoma, and other malignancies.[47-49] The duration of administration of adjuvant therapy varies depending on the type of cancer being treated and the drugs being used but is typically several weeks to months in duration. See subsequent chapters for a specific discussion of the use of adjuvant therapy in solid tumor malignancies. For F.R., the recommendation will be to receive adjuvant chemotherapy with six to eight cycles of carboplatin and paclitaxel.

Because it is difficult to detect micrometastases or residual disease, it is a challenge to determine which patients should receive adjuvant therapy. To help with these decisions, clinicians frequently consider histologic and cytogenetic characteristics of the primary tumor that are associated with high risk of relapse.

Neoadjuvant therapy

Neoadjuvant therapy is given before the primary treatment (typically, surgery or radiation) in patients who present with locally advanced tumors that are unlikely to be cured with primary therapy alone (eg, large tumors or those that are impinging on surrounding vital structures). The objective of neoadjuvant therapy is to reduce the tumor mass, thereby increasing the likelihood of eradication by subsequent surgery or radiation. Neoadjuvant therapy can lessen the amount of radical surgery the patient needs, which can preserve cosmetic appearance and function of the surrounding normal tissues. The tumor can be resistant to neoadjuvant therapy and continue to grow, however, making surgery or radiation even more difficult. Patients may also experience toxicities with neoadjuvant therapy that may delay surgery or impair postsurgical healing. Locally advanced tumors in which neoadjuvant therapy has been

shown to improve outcomes include non–small cell lung cancer, breast cancer, soft tissue sarcomas, esophageal cancers, bladder cancer, and osteogenic sarcoma.[47,50–54] See subsequent chapters for a specific discussion of the use of neoadjuvant therapy in solid tumors.

CASE 93-9

QUESTION 1: H.P. is a 57-year-old male who is currently undergoing a staging workup for a presumed diagnosis of metastatic adenocarcinoma of the lung. He has heard that cytotoxic "chemotherapy is the only thing available to treat metastatic cancer."

What other agents are being used to treat cancer besides those that are considered cytotoxic?

TARGETED THERAPY

By understanding the mechanisms by which cancer cells exhibit unregulated growth and immortality and possess the ability to invade tissues and metastasize, it has been possible to design drugs that inhibit these processes.

Monoclonal antibodies

Directed at specific receptors associated with cancer, monoclonal antibodies block ligands from binding to their targets. Unlike traditional chemotherapy, monoclonal antibodies selectively target receptors or their ligands known to potentiate cancer pathways and, as a result, minimize toxicity to noncancer cells. **Table 93-6** provides a list of monoclonal antibodies currently approved by the U.S. Food and Drug Administration (FDA) to treat malignancy.[34]

Table 93-6
Monoclonal Antibodies

Class[a]	Agent (Trade Name)	Mechanism of Action	Notable Toxicities
Anti-CD19, Anti-CD3	Blinatumomab	Binds to CD19 on B cells and CD3 on T cells; causes formation of cytolytic synapses between B and T cells	Neurotoxicity; infection; tremor; fever; edema, rash; nausea, diarrhea, constipation; cytokine release syndrome
Anti-CD20	Obinutuzumab	Binds to CD20 on B cells; induces cell death via ADCC, CDC, and antibody-dependent cellular phagocytosis	Myelosuppression; hepatic and renal dysfunction; electrolyte abnormalities; infection; infusion reaction
	Ofatumumab	Binds to CD20 on B cells at different binding sites than does rituximab; induces cell death via ADCC and CDC	Cough; diarrhea, nausea; fatigue; myelosuppression; hypersensitivity reaction, pyrexia; rash; infection
	Rituximab	Binds to CD20 on B cells; induces cell death via ADCC and CDC	Hypersensitivity reaction; myelosuppression; infection; tumor lysis syndrome

Anti-CD20 Radiation	Ibritumomab tiuxetan	Yttrium-90 (Y-90) linked to rituximab; binds to CD20 on B cells and releases radiation (β particles); induces cell damage via free radicals	Infusion-related reaction; chills, nausea; fatigue; myelosuppression; see notable toxicities for rituximab
Anti-CD22	Inotuzumab ozogamicin	Binds to CD22 and is internalized; calicheamicin derivative is released inside the myeloid cell, resulting in double-strand breaks, inducing cell cycle arrest and apoptosis.	Hepatotoxicity, QT prolongation, hemorrhage, myelosuppression, infusion-related reaction, fatigue, infection, fever
Anti-CD30	Brentuximab vedotin	Three-component antibody drug conjugate; binds to cells expressing CD30 and is internalized; MMAE is then released, which disrupts the microtubule network.	Myelosuppression; peripheral neuropathy; fatigue; nausea, vomiting, diarrhea; fever; rash; upper respiratory infection
Anti-CD33	Gemtuzumab ozogamicin	Binds to CD33 and is internalized; calicheamicin derivative is released inside the myeloid cell resulting in double-strand breaks, inducing cell cycle arrest and apoptosis.	Hepatotoxicity, QT prolongation, myelosuppression, hemorrhage, hypersensitivity reaction, nausea, constipation, fatigue, fever
Anti-CD38	Daratumumab	Binds to CD38; induces apoptosis directly through Fc-mediated cross-linking as well as by immune-mediated tumor cell lysis through CDC, ADCC, and antibody-dependent cellular phagocytosis.	Infusion-related reaction, hepatitis B reactivation, cough, fever, arthralgia, myelosuppression
Anti-EGFR	Cetuximab	Binds to EGFR, preventing activation and inhibiting cell proliferation	Papulopustular rash, pruritus; fatigue; hypersensitivity reactions; abdominal pain, nausea, diarrhea; hypomagnesemia; paronychia
	Panitumumab	Binds to EGFR with higher affinity than does cetuximab, preventing activation and inhibiting cell proliferation	
Anti-HER2	Ado-trastuzumab emtansine	HER2-antibody drug conjugate of trastuzumab and microtubule inhibitor DM1; binds to HER2, inducing cell cycle arrest and cell death	Myelosuppression, nausea, constipation, diarrhea; fatigue, peripheral neuropathy; hypokalemia, fever
	Pertuzumab	Binds to HER2, inhibiting HER2 dimerization and downstream signaling, halting cell growth	Myelosuppression; cardiomyopathy; fatigue, alopecia; nausea, vomiting, diarrhea
	Trastuzumab	Binds to HER2; induces cell death via ADCC	Cardiomyopathy; nausea, vomiting, diarrhea; infusion-related reaction
Anti-VEGF	Bevacizumab	Binds to and inhibits VEGF ligand interaction with receptors, blocking angiogenesis	Hypertension; proteinuria; infusion-related reaction; bleeding; thrombosis; gastrointestinal perforation, impaired wound healing
	Ramucirumab	Binds to and inhibits VEGF2 ligand interaction with receptors (VEGF-A, VEGF-C, VEGF-D), blocking angiogenesis	
Immune Checkpoint Inhibitors	Ipilimumab	Enhances T-cell activation and proliferation by inhibiting CTLA-4, restoring antitumor immune response	Fatigue; nausea, anorexia, diarrhea, colitis; pruritus, rash; hepatic dysfunction; hypophysitis
	Nivolumab	Enhances T-cell activation and proliferation by inhibiting PD-1 activity, which is a negative regulator of T-cell pathways; restores antitumor immune response	Rash, pruritus; nausea, constipation, diarrhea; fatigue; electrolyte abnormalities; hepatic dysfunction; musculoskeletal pain; cough, pneumonitis, hypophysitis
	Pembrolizumab		
	Cemiplimab		
	Atezolizumab	Enhances T-cell activation and proliferation by binding to PD-L1 to prevent the interaction between the PD-1 and CD80 receptors; restores antitumor immune response	
	Avelumab		
	Durvalumab		

Other	Dinutuximab (Unituxin®)	Cell lysis of GD-2-expressing neuroblastoma cells via ADCC and CDC	Myelosuppression; urticaria; diarrhea, nausea, vomiting; hepatotoxicity; fever; capillary leak syndrome; infusion-related reaction; peripheral neuropathy
	Elotuzumab	Directed against SLAMF7; mediates ADCC, which increases antitumor activity through the increased activation of natural killer cells	Hepatotoxicity, infusion-related reaction, infection, fatigue, hyperglycemia, diarrhea, cough, fever
	Mogamulizumab	Selectively binds to CCR4 and targets a cell for ADCC	Infusion-related reaction, myelosuppression, autoimmune toxicity, rash, hyperglycemia, hepatic dysfunction, diarrhea
	Polatuzumab vedotin	Three-component antibody drug conjugate; binds to cells expressing CD79b and is internalized; MMAE binds to the tubules, which disrupts the cellular microtubule network.	Infusion-related reaction, myelosuppression, peripheral neuropathy, hepatotoxicity, diarrhea, opportunistic infection, fever, renal dysfunction

ADCC, antibody-dependent cellular toxicity; CCR4, C-C chemokine receptor 4; CDC, complement-dependent cytotoxicity; CTLA-4, cytotoxic T-lymphocyte-associated antigen-4; EGFR, epidermal growth factor receptor; HER, human epidermal growth factor receptor; MMAE, monomethyl auristatin E; PD-1, programmed cell death-1; PD-L1, programmed death ligand 1; SLAM7, signaling lymphocytic activation molecule family member 7; VEGF, vascular endothelial growth factor.

[a]All monoclonal antibodies are administered intravenously, IV.

Tyrosine kinase inhibitors

Tyrosine kinase inhibitors (TKIs) are small molecules that directly inhibit tyrosine kinase activation by competing with ATP for binding to the intracellular tyrosine kinase domain. Advantages of these inhibitors include inhibiting cells that may not overexpress the receptor on their surface or have mutated forms of the receptor that result in its activation and direct inhibition of cell signaling. Even though most TKIs are designed to inhibit a single target, they often have inhibitory properties for additional molecules, which could affect an internal cascade of biologic activity, resulting in antitumor activity and toxicity.

This class of drugs is taken orally. Owing to varying pharmacokinetics, specific instructions on self-administration should be provided to patients (eg, take on an empty stomach or take with a full meal). In addition, many TKIs are substrates, inhibitors, and inducers of CYP450 enzymes as well as substrates or inhibitors of transporter proteins such as P-glycoprotein, breast cancer resistance protein (BCRP), and multidrug and toxic compound extrusion 1/2

(MATE1/2). Attention to potential drug interactions is crucial to safe medication use.

Table 93-7 provides the TKIs currently approved by the FDA to treat malignancies.[34]

Table 93-7
Tyrosine Kinase Inhibitors

Class[a]	Agent	Mechanism of Action	Notable Toxicities
ALK Inhibitors			
	Alectinib Brigatinib Ceritinib Crizotinib Lorlatinib	Inhibits ALK, thereby reducing tumor cell proliferation in cells expressing ALK fusion protein; also inhibits ROS1 kinase	Muscle pain, visual disturbances; liver enzyme elevations; diarrhea, nausea, vomiting; fatigue, pneumonitis; blood glucose and cholesterol elevation
BCR-ABL Inhibitors			
	Bosutinib Dasatinib Imatinib Nilotinib Ponatinib	Inhibits BCR-ABL kinase, c-KIT, and PDGFR kinases	Myelosuppression; nausea, vomiting, diarrhea; fatigue; dermatologic toxicity; muscle pain; swelling
BTK Inhibitors			
	Acalabrutinib Ibrutinib Zanubrutinib	Inhibits the BTK of the B-cell receptor signaling pathway	Myelosuppression; nausea, diarrhea; fatigue, edema, fever; dermatologic toxicity; musculoskeletal pain; tumor lysis syndrome

CSF1R Inhibitors			
	Pexidartinib	Inhibits overexpressed CSF1R ligand	Fatigue; hair discoloration, increase in cholesterol and LDH; myelosuppression; eye swelling
EGFR Inhibitors			
	Afatinib Dacomitinib Erlotinib Gefitinib Osimertinib	Inhibits EGFR TK; resulting in tumor growth inhibition	Rash, dry skin, pruritus; paronychia; diarrhea
FGFR Inhibitors			
	Erdafitinib Pemigatinib	Inhibits FGFR TK	Fatigue, dermatologic toxicity; electrolyte disturbance; stomatitis, diarrhea; myelosuppression; increase in creatinine
FLT3 Inhibitors			
	Gilteritinib Midostaurin	Inhibits signaling and proliferation of cells expressing FLT3	Liver enzyme elevation; fatigue; rash; nausea; headache; febrile neutropenia
HER2 Inhibitors			
	Lapatinib Neratinib Tucatinib	Inhibits HER2 and EGFR TK	Nausea, diarrhea; dermatologic toxicity; myelosuppression; hepatic toxicity; cardiomyopathy, QT prolongation; pulmonary toxicity
JAK Inhibitors			
	Fedratinib Ruxolitinib	Inhibits hematopoiesis and immune function mediated by JAK	Myelosuppression; liver enzyme elevation; diarrhea, nausea; muscle pain
MET Inhibitors			
	Capmatinib	Inhibit MET TK from the mutant variant produced by exon 14 skipping	Swelling, fatigue; liver enzyme elevation; nausea, vomiting; chest pain
NTRK Inhibitors			
	Entrectinib Larotrectinib	Inhibits NTRK1, 2, and 3 TK	Fatigue; liver enzyme elevation; anemia; constipation, diarrhea; muscle pain; visual disturbance
PDGFRA Inhibitors			
	Avapritinib Ripretinib	Inhibits PDGFRA and KIT TK	Fatigue; electrolyte disturbance; myelosuppression; neuropathy; liver enzyme elevation
RET Inhibitors			
	Pralsetinib Selpercatinib	Inhibits RET TK including wild-type, fusion-variant, and mutant variant	Liver enzyme elevations; abdominal discomfort, nausea, vomiting; swelling; hypertension; change in lipid and glucose; myelosuppression
VEGF Inhibitors			
	Axitinib Cabozantinib Lenvatinib Pazopanib Regorafenib Sorafenib Sunitinib Vandetanib	Inhibits VEGF receptor tyrosine kinases, thereby blocking angiogenesis and tumor growth	Hypertension; diarrhea, nausea, vomiting; liver enzyme elevation; hand–foot syndrome, dermatologic toxicities; fatigue

ALK, anaplastic lymphoma kinase; BCR-ABL, breakpoint cluster region-ABL1 fusion gene; BTK, Bruton tyrosine kinase; CSF1R, colony-stimulating factor 1 receptor; EGFR, epidermal growth factor receptor; FGFR, fibroblast growth factor receptor; FLT-3, Fms-like tyrosine kinase 3; HER2, human epidermal growth factor receptor 2; JAK, Janus-associated kinase; KIT, tyrosine-protein kinase kit; LDH, lactate dehydrogenase; MET, proto-oncogene c-Met; NTRK, neurotrophic receptor tyrosine kinase; PDGFR, platelet-derived growth factor; PDGFRA, platelet-derived growth factor a; RET, c-RET oncogene; ROS1, c-ros oncogene 1; TK, tyrosine kinase; VEGF, vascular endothelial growth factor.

[a]All tyrosine kinase inhibitors are administered orally, PO.

Other targeted therapy

Because of increasing information regarding signal transduction pathways and cellular growth and proliferation, more drugs that target these key molecules are being developed. Histone deacetylase (HDAC) inhibitors, mammalian target of rapamycin (mTOR) inhibitors, and proteasome inhibitors are examples of drugs that have novel mechanism(s) of action. **Table 93-8** lists these and other targeted agents currently approved by the FDA to treat malignancies.[34]

Table 93-8
Other Targeted and Miscellaneous Agents

Class	Agent	Mechanism of Action	Notable Toxicities
BCL-2 Inhibitor			
	Venetoclax	Inhibits antiapoptotic protein BCL-2 overexpression on CLL and AML cells	Myelosuppression; fatigue; liver enzyme elevation; swelling; tumor lysis syndrome
BRAF Inhibitors			
	Dabrafenib Encorafenib Vemurafenib	Blocks cellular proliferation of mutated BRAF	Dermatologic toxicity; nausea, diarrhea; edema; headache; hepatic dysfunction; fever, chills; secondary skin cancer
CDK Inhibitors			
	Abemaciclib Palbociclib Ribociclib	Inhibits cell cycle progression by blocking CDK 4 and 6	Myelosuppression, infection, fatigue; nausea, vomiting, diarrhea; stomatitis, alopecia; thrombosis
HDAC Inhibitors			
	Belinostat Panobinostat Romidepsin Vorinostat	Inhibits HDAC resulting in accumulation of acetyl groups, cell cycle arrest, and apoptosis	Nausea, vomiting; fatigue; myelosuppression; fever; peripheral edema; ECG changes
Hedgehog Inhibitors			
	Glasdegib Sonidegib Vismodegib	Inhibits cell growth and differentiation in embryogenesis mediated by hedgehog pathway	Fatigue; appetite loss; hair loss and thinning; dysgeusia; embryofetal death
IDH1 Inhibitors			
	Ivosidenib	Inhibitor-mutated isocitrate dehydrogenase 1 in leukemia cells	Differentiation syndrome; QT prolongation; muscle pain; gastrointestinal discomfort
IDH2 Inhibitors			
	Enasidenib	Inhibitor-mutated isocitrate dehydrogenase 2 in leukemia cells	Differentiation syndrome; gastrointestinal discomfort; increase in bilirubin
Immunomodulating Agents			
	Lenalidomide Pomalidomide Thalidomide	Immunomodulatory and angiogenic effects	Fatigue; teratogenic potential; thromboembolism; arthralgias
MEK Inhibitors			
	Binimetinib Cobimetinib Selumetinib Trametinib	Decreased cell proliferation and increased apoptosis by inhibiting MEK activation, which is a downstream effector of BRAF (mutant)	Cardiomyopathy; acneiform rash; diarrhea; hepatic dysfunction; edema; QT prolongation; hypoalbuminemia
mTOR Inhibitors			
	Everolimus Temsirolimus	Inhibits mTOR kinase, VEGFR	Fatigue, nausea, anorexia; dermatologic toxicity; hyperlipidemia, hyperglycemia, electrolyte abnormalities; stomatitis; myelosuppression, infection; pneumonitis
PARP Inhibitors			
	Niraparib Olaparib Rucaparib Talazoparib	Inhibits DNA transcription, cell cycle regulation, and DNA repair associated with PARP	Nausea, vomiting, fatigue; myelosuppression; musculoskeletal pain; thrombosis; upper respiratory infection; interstitial lung disease; secondary malignancy

PI3K Inhibitors			
	Alpelisib Copanlisib Duvelisib Idelalisib	Inhibits PI3K TK to induce apoptosis and cell death	Myelosuppression; nausea, diarrhea, colitis, gastrointestinal perforation; fatigue; hepatic toxicity; pulmonary toxicity
Proteasome Inhibitors			
	Bortezomib Carfilzomib Ixazomib	Inhibits proteasomes, enzymes that regulate protein homeostasis within cells	Nausea, diarrhea, constipation; peripheral neuropathy; headache, fatigue, fever; myelosuppression; herpes zoster reactivation
VEGF Inhibitors			
	Ziv-Aflibercept	Fusion protein comprising VEGF receptor-binding domains, acting as a decoy receptor for VEGF, inhibiting angiogenesis	Fatigue, diarrhea, stomatitis; myelosuppression; hypertension, proteinuria; bleeding, impaired wound healing; thrombosis; gastrointestinal perforation

AML, acute myeloid leukemia; BCL-2, B-cell lymphoma 2; BRAF, proto-oncogene b-Raf; CDK, cyclin-dependent kinase; CLL, chronic lymphocytic leukemia; DNA, deoxyribonucleic acid; ECG, electrocardiogram; HDAC, histone deacetylase; IDH, isocitrate dehydrogenase; MEK, mitogen-activated protein kinase (MAPK)/extracellular signal-regulated kinase (ERK) kinase; mTOR, mammalian target of rapamycin; PARP, poly ADP-ribose polymerase; PI3K, phosphatidylinositol 3-kinase; TK, tyrosine kinase; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor.

Combination therapy with targeted agents

The optimal activity of adding targeted agents to cytotoxic chemotherapy is difficult to predict. Knowledge about how to combine targeted agents with chemotherapy is limited, although clinical investigations are ongoing. See subsequent chapters for a specific discussion of the use of targeted therapy with chemotherapy in solid tumor and hematologic malignancies.

ENDOCRINE THERAPY

Endocrine therapy can be used to treat several common cancers, including breast, prostate, and endometrial cancers, which arise from hormone-sensitive tissues (**Table 93-9**). These tumors grow in response to endogenous hormones that trigger growth signals. Current endocrine therapies inhibit tumor growth by blocking hormone receptors or by eliminating endogenous hormone feeding the tumor. Not all tumors arising from hormone-sensitive tissues respond to endocrine manipulation. Lack of response may be associated with hormone-resistant tumor cells or inadequate suppression of the endogenous feeding hormones.[55]

Table 93-9
Endocrine Therapies

Class and Agents	Mechanism of Action	Class Toxicities
Androgens	Synthetic derivative of testosterone; suppresses GnRH, LH, FSH by a negative feedback system	Deepening voice, alopecia, hirsutism, facial or truncal acne, fluid retention, menstrual irregularities, cholestatic jaundice
Antiandrogens Bicalutamide (PO) Flutamide (PO) Nilutamide (PO)	Nonsteroidal antiandrogens that work to interfere with testosterone effects	Hot flashes; breast tenderness; hepatic dysfunction; diarrhea; fatigue; edema; hypertension; arthralgias
Enzalutamide (PO) Apalutamide (PO) Abiraterone (PO)	Inhibits androgen receptor translocation, leading to cellular apoptosis Inhibits formation of the testosterone precursors, DHEA and androstenedione	
Antiestrogens Fulvestrant (IM) Tamoxifen (PO)	Competitive binding of estrogen receptors produces downregulation of estrogen receptors.	Liver enzyme elevation; headache; hot flashes; myalgia, arthralgia; nausea; vomiting; thromboembolism
Aromatase Inhibitors Anastrozole (PO) Letrozole (PO) Exemestane (PO)	Competitive binding of estrogen receptors produces downregulation of estrogen receptors.	Hot flashes; nausea; fatigue, insomnia; increased risk of bone fractures; arthralgia
Estrogens Ethinyl estradiol (PO) Conjugated estrogens (PO)	Suppresses androgen synthesis, as well as secretions of gonadotropins, FSH, and LH via negative feedback system	Nausea, vomiting, fluid retention, hot flashes, anorexia, thromboembolism, hepatic dysfunction

Class and Agents	Mechanism of Action	Class Toxicities
GnRH Analogs (LHRH Agonists) Goserelin (SC) Histrelin (SC) Triptorelin (IM) Leuprolide (IM; SC)	Downregulates GnRH receptor on the pituitary gland, decreasing secretion of FSH and LH	Amenorrhea, hot flashes, sexual dysfunction; nausea, edema; tumor flare; injection-site reaction; osteoporosis
GnRH Antagonists Degarelix (SC)	Binds to GHRH receptors on the pituitary gland, blocking the secretion of FSH and LH	Hot flashes; hepatic toxicity; injection-site reaction
Progestins Medroxyprogesterone (PO) Megesterol acetate (PO)	Promotes differentiation and maintenance of endometrial tissue	Weight gain, edema; hot flashes, vaginal bleeding; thrombosis

CYP, cytochrome; DHEA, dehydroepiandrosterone; FSH, follicle-stimulating hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; IM, intramuscular; LH, luteinizing hormone; LHRH, luteinizing hormone–releasing hormone; PO, oral; SC, subcutaneous.

IMMUNOTHERAPY

Immune therapy comprises substances that stimulate the body's immune system to identify circulating tumor cells. Some agents target certain cells of the immune system; other agents are more nonspecific.[33] An individual's immune system plays a crucial role in developing or eradicating cancer. Normally, an intact immune system can protect the host against malignant cells and infectious pathogens, but current evidence shows that individuals with "weakened" immune systems are at an increased risk for developing cancer. Common immunotherapy classes include checkpoint inhibitors and immune effector cell therapy (**Table 93-10**; also see Table 93-6), but can also include vaccines and cytokines.

Table 93-10
Immune Effector Cell Therapy

Class	Agent	Mechanism of Action	Notable Toxicities
Chimeric antigen receptor T-cell (CAR-T) immunotherapy	Axicabtagene ciloleucel	Genetically modified autologous T cells reprogrammed with a transgene encoding a CAR; binds to CD19 cells and activates costimulatory domains to cause T-cell activation and proliferation; results in antitumor activity and cell destruction	Cytokine release syndrome, neurologic toxicity, myelosuppression, infection, hypersensitivity reaction, fever, hypotension, decreased appetite
	Brexucabtagene autoleucel		
	Tisagenlecleucel		

If H.P. is in fact diagnosed with stage IV adenocarcinoma of the lung, he may receive other agents besides chemotherapy during the course of treatment for his disease. For a specific discussion of which noncytotoxic agents H.P. may receive, refer to Chapter 98, Lung Cancer.

Administration

Systemic CHEMOTHERAPY

Systemic chemotherapy is most commonly administered by the intravenous route, either as a bolus injection (generally >15 minutes), short infusion (15 minutes to several hours), or as a continuous infusion (lasting 24 hours to several weeks). Some chemotherapy can also be administered orally, intramuscularly, or subcutaneously.

Targeted agents are most commonly administered intravenously or orally. Monoclonal antibodies are primarily administered intravenously, whereas small-molecule TKIs are primarily administered orally. Endocrine agents are primarily administered orally or subcutaneously.

Although chemotherapy was initially developed for systemic use, techniques have been developed to administer agents directly to specific sites of the body affected by the tumor (**Table 93-11**). Regionally or locally administered chemotherapy allows for high concentrations of drug at the tumor site while reducing systemic exposure and subsequent toxicity. However, a potential disadvantage is that distant micrometastases may not be exposed to chemotherapy, allowing continued growth of tumor cells.

Table 93-11
Regional or Local Routes of Chemotherapy Administration

Route of Administration	Cancer Managed With Alternative Route
Intrathecal or intraventricular	Leukemia, lymphoma
Intravesicular	Bladder
Intraperitoneal	Ovarian
Intrapleural	Malignant pleural effusions
Intra-arterial	Melanoma, sarcoma
Hepatic artery	Liver metastases
Chemoembolization (intra- arterial or intravenous)	Colon, rectal, carcinoid, liver metastases

Assessing Response to Therapy

CASE 93-10

QUESTION 1: G.K. is a 67-year-old female who was recently diagnosed with metastatic breast cancer. Her symptoms include widespread pain, anorexia, and fatigue. She has received two cycles of treatment with a combination chemotherapy regimen. A recent CT scan of her abdomen showed marked shrinkage at several tumor sites, and her pain has decreased.

How long should she continue to receive this chemotherapy?

An important step in the treatment process is assessing response to treatment. This assessment should include evaluation of efficacy and toxicity, including impact on the patient's overall quality of life. Reevaluation should occur at regularly scheduled intervals and include physical examination, laboratory tests, and repeat diagnostic imaging.

Response Evaluation Criteria in Solid Tumors (RECIST) was introduced in 2000 to unify response assessment criteria, define how to choose evaluable tumors, and enable the use of new imaging technologies (spiral CT and MRI). RECIST guidelines have since been updated to account for changes in evaluating tumors and the use of immunotherapy. The World Health Organization, National Cancer Institute, and European Organization for Research and

Treatment of Cancer have adopted RECIST criteria as the standard for evaluating tumor response (**Table 93-12**).[56]

Table 93-12

Response Criteria for Evaluating Effects of Chemotherapy of Target Lesion

Complete Response
Disappearance of all target lesions. Any pathologic lymph nodes (whether target or nontarget) must have a reduction in short axis to >10 mm.
Partial Response
At least a 30% decrease in the sum of diameters of target lesions, taking as reference the baseline sum diameters
Progressive Disease
At least a 20% increase in the sum of diameters of target lesions, taking as reference the smallest sum on study (this includes the baseline sum if that is the smallest on study). In addition to the relative increase of 20%, the sum must demonstrate an absolute increase of at least 5 mm. The appearance of one or more new lesions is also considered progression.
Stable Disease
Neither sufficient shrinkage to qualify for partial response nor sufficient increase to qualify for progressive disease, taking as reference the smallest sum diameters while on study

Response Evaluation Criteria in Solid Tumors (RECIST) version 1.1.

Several standardized toxicity grading scales are available to assess toxicity associated with chemotherapy. However, the National Cancer Institute Common Toxicity Criteria for Adverse Events is the most commonly used.[29,57] Toxic effects of systemic therapy is further discussed in Chapter 94, Adverse Effects of Chemotherapy, Immunotherapy, and Targeted Agents.

Because toxicities associated with systemic therapy are potentially severe, it is important to evaluate the risks and benefits. The benefits of a treatment regimen should outweigh the negative effects it has on the physical, mental, and social well-being of the patient. To monitor a patient's quality of life, several comprehensive assessment tools have been developed.[58] In addition, other clinical benefits (eg, reduced pain, decreased use of analgesics, weight gain, and improved performance status) have been recognized by the FDA as

acceptable criteria for measuring the quality of life. These criteria are also considered when evaluating new agents for approval.

G.K. should continue to receive the same therapy if her tumor is responding and she does not experience intolerable or life-threatening treatment-related toxicities. For some cancers, continued therapy after a certain number of cycles is not associated with further benefit because toxicity becomes an overriding issue.

TUMOR MARKERS

Tumor markers are substances found in tumor tissue or released from the tumor into the blood or other body fluids (eg, urine).[33] However, not all cancers have relevant tumor markers. The ideal tumor marker should be produced and released primarily by cancer cells (or by other tissues in response to the tumor) at levels proportional to the tumor mass, and a reduction in the level of the marker should be seen in response to treatment. In addition, the ideal tumor marker should be measurable at very low levels, allowing for detection of the tumor at lower volumes than conventional diagnostic imaging permits.[59] Because most tumor markers lack specificity and may be elevated owing to other causes, they are often not useful as a sole screening or diagnostic test and are instead used to detect recurrent disease. **Table 93-13** lists some of the common tumor markers used in practice.

Table 93-13
Clinically Useful Tumor Markers

Tumor Markers	Cancers Commonly Associated With Increased Markers
CA-19-9	Pancreatic
CA-15-3, CA-27-29	Breast
α-Fetoprotein (AFP)	Liver, testicular, ovarian
CA-125	Ovarian
Carcinoembryonic antigen (CEA)	Colon, lung

Tumor Markers	Cancers Commonly Associated With Increased Markers
Human chorionic gonadotropin (hCG)	Trophoblastic, testicular
β_2-Microglobulin	Multiple myeloma
Prostate-specific antigen (PSA)	Prostate

HANDLING OF CYTOTOXIC DRUGS

Impact on the Pharmacy

CASE 93-11

QUESTION 1: The administrator of an outpatient care clinic recently announced that two medical oncologists will be joining the staff. Previously, patients were referred to outside oncologists, and no cytotoxic drugs were prepared or administered at this clinic.

What implications will the addition of these physicians have on the pharmacy department?

Addition of cancer treatment to institutional services will affect three areas of the pharmacy department: budget, policies and procedures for safe drug handling and disposal, and the staff education program. The pharmacy department will need to increase its budget to accommodate additional personnel and purchase new equipment, supplies, supportive care medicines, and chemotherapy agents. To estimate the projected budget increase, pharmacy leadership should meet with the oncologists to discuss the anticipated volume of chemotherapy orders including systemic therapy and supportive care medicines (eg, antiemetic therapy, analgesics, growth factors) likely to be prescribed. All new systemic therapy agents and supportive care medicines should be added to the institutional formulary. In addition, projected use of investigational

agents, clinical pharmacy services needed, and any plans to develop an ambulatory infusion program should be determined. Institutional policies and procedures to ensure safe handling of chemotherapy agents must be created. These should be conveyed to all personnel affected through a staff education program because safe handling of chemotherapy agents is critical in decreasing the risk of medication errors and injuries.

Medication Errors

Chemotherapy-related medication errors have brought significant attention to the entire drug use process in oncology, and have identified several factors that appear to contribute to the risk. Use of abbreviations, verbal orders, multiple-day regimens, incorrect references and protocols, and illegible medication orders has contributed to medication errors. Increasing use of computerized prescriber order entry and standardized preprinted orders have helped eliminate many errors. Several groups have responded to the problem by issuing policy recommendations to minimize such errors.[60–65]

Risks

Case 93-11, Question 2: What are the potential risks of handling cytotoxic drugs? What resources are available to assist the pharmacy director and the pharmacy staff in the development of policies and procedures?

Many of these agents are carcinogenic, teratogenic, or mutagenic in animal models and in humans at therapeutic doses.[65] Danger to health care personnel handling such agents results from inherent toxicities of the agents and the extent (ie, amount and length of time) to which the workers are exposed during drug handling.[65] Various studies have attempted to assess the effect of occupational exposure to hazardous drugs on health care workers. These studies measured urine mutagenicity, chromosomal damage, blood

concentrations, and the level of contamination that occurs in the work areas used for drug preparation and administration.[65–67] These studies indicate that urine mutagenicity and chromosomal damage in workers may be a direct result of cytotoxic exposure. Other reports have correlated reproductive risks (eg, infertility or increased risk of miscarriage) and birth defects in pregnant workers handling cytotoxic drugs.[66,68] Findings from these reports together with the toxicities observed in patients receiving therapeutic doses led the American Society of Health-System Pharmacists to conclude that health care workers exposed to hazardous drugs may be absorbing or inhaling these drugs and may be at risk for adverse outcomes.[65]

In response to concerns regarding occupational exposure to hazardous drugs, several groups have published guidelines for the safe handling of these agents in the workplace (ie, storage, preparation, administration, and disposal).[65,67] These guidelines will be helpful to the pharmacy department when developing policies and procedures.

Policies and Procedures

Case 93-11, Question 3: What specific policies and procedures are necessary? What other departments should be consulted during the development and implementation of the handling guidelines?

Policies that address the entire scope of potential occupational exposures within the workplace must be developed. These policies should include (a) a worker's "right to know" regarding potential hazards; (b) education and training for workers involved with hazardous drug handling; (c) quality assurance to monitor adherence to safe handling procedures; and (d) guidelines for workers who are attempting to conceive a child, become pregnant, or are nursing.

Specific procedures that outline appropriate handling of hazardous agents during all aspects of institutional storage, use, and disposal should be developed. These procedures should address appropriate (a) storage in the receiving and storeroom areas, (b) preparation and

administration of parenteral formulations, (c) manipulation and dispensing of oral and topical formulations, (d) cleanup of spills, (e) management of acute exposures, and (f) disposal of hazardous agents and supplies used to prepare and dispense chemotherapy. If the oncology program includes ambulatory infusion or home care components, procedures should also be developed for appropriate handling and disposal of these products in the home. Handling of oral chemotherapy and biotherapy must also be specifically addressed. Policies should include processes for cleaning of tools and nondisposable items used to dispense oral cytotoxic agents to minimize contamination with other drugs.[69]

Other departments may be affected by these guidelines, including medical staff, nursing, environmental services staff (in the cleanup of spills and equipment), maintenance (upkeep of equipment), and the receiving area (where cytotoxic drugs may be received from suppliers). The institutional safety office and legal staff also should be consulted to help devise the policies and procedures.

Necessary Equipment and Supplies

Case 93-11, Question 4: What equipment and supplies are necessary for handling hazardous drugs?

Proper equipment and supplies can minimize occupational exposure in the health care workplace by protecting both the worker and the environment. All handling guidelines recommend that manipulations (eg, reconstitution and admixing) of hazardous drugs be done in the class I to III biologic safety cabinet to provide maximal protection for the worker and the work environment. Workers must wear two pairs of chemotherapy gloves, protective boot covers, hair cover, mask, and a disposable gown of lint-free, low-permeability fabric with long sleeves, knit cuffs, and back closure. In addition, only syringes and intravenous sets with threaded Luer-Lock™ connections should be used.[70] Final products (eg, syringes, intravenous bags, or bottles) should be placed in sealable containers such as zipper-

closure plastic bags to prevent accidental spillage and clearly labeled as a hazardous drug. The United States Pharmacopeia dictates guidelines for safe handling of hazardous drugs and compounding sterile products.[71,72]

Disposal of hazardous waste requires specific receptacles, which should be placed in all areas where workers handle these drugs. Disposal of these agents should follow institutional, state, and local regulations. Materials for the cleanup of spills (eg, absorbent material, plastic bags or containers, and protective garments) also must be available in all areas where hazardous drugs are stored, prepared, or administered.

94

Adverse Effects of Chemotherapy, Immunotherapy, and Targeted Agents

Victoria Nachar and Matthew Newman

CORE PRINCIPLES		CHAPTER CASES
1	Myelosuppression is one of the most common toxicities of anticancer therapy. Anticancer therapy may impact one or all the bone marrow cell lines including erythrocytes, neutrophils, and platelets. Complications from anemia, neutropenia, and thrombocytopenia can cause significant morbidity and mortality. Prophylactic administration of growth factors may protect against the myelosuppressive effects of chemotherapy.	**Case 94-1 (Questions 1–4)**

CORE PRINCIPLES		CHAPTER CASES
2	The upper and lower gastrointestinal (GI) tract is highly susceptible to anticancer therapy, and toxicities can include nausea and vomiting, mucositis, xerostomia, constipation, and diarrhea. Efficacy of preventive strategies is limited; thus, supportive treatment is a foundation for managing adverse effects in patients.	**Case 94-2 (Questions 1–3) Case 94-3 (Question 1)**
3	Dermatologic toxicities from anticancer therapies include alopecia, nail changes, hyperpigmentation, radiation sensitivities, hand–foot syndrome, dry skin, and papular–pustular (acneiform) rash. Most of the toxicities are cosmetic and resolve upon discontinuation of the agent. Onset and duration of dermatologic toxicities depend on the causative agent. Treatment is supportive.	**Case 94-4 (Questions 1–4)**
4	Extravasation is the unintended infiltration of an agent into the tissue area surrounding the vein during an infusion. Extravasations require emergency treatment that is agent specific.	**Case 94-4 (Questions 5, 6), Tables 94-1, 94-2**

CORE PRINCIPLES		CHAPTER CASES
5	Many anticancer therapies are associated with immunoglobulin E–mediated hypersensitivity reactions. Monoclonal antibodies are among some of the agents most commonly associated with reactions. Reactions commonly occur with the first dose, and they may be minimized with premedications.	**Case 94-5 (Question 1), Table 94-3**
6	Chimeric antigen receptor T-cell (CAR-T) therapies and other immune-directed therapies may cause cytokine release syndrome or neurotoxicity, requiring careful intervention. Immune checkpoint inhibitors are associated with distinct toxicities, including pneumonitis, colitis, and dermatitis, which may warrant therapy interruption, systemic steroids, or other immunosuppressive supportive care agents.	**Case 94-6 (Question 1), Table 94-4**
7	Multiple types of central nervous system (CNS) toxicity, including encephalopathy, cerebellar toxicity, and peripheral neuropathy, are associated with anticancer agents, and differ in presentation between various agents. Most of the symptoms of neurotoxicity are reversible over time, but modifications to regimens, including discontinuation of agents or reduction of doses, may be necessary.	**Case 94-7 (Questions 1–4), Table 94-5**

CORE PRINCIPLES		CHAPTER CASES
8	Cardiomyopathy, arrhythmias, and hypertension are common types of cardiotoxicity observed in patients receiving infusion and oral anticancer therapies. Anthracycline-induced cardiomyopathy is closely linked to a patient's cumulative dose and may be treated with current heart failure medications.	**Case 94-8 (Questions 1–4)**
9	Several anticancer agents carry severe risks of nephrotoxicity and bladder toxicity for which preventive measures are necessary. Cisplatin is one of the most nephrotoxic agents. Preventive strategies for cisplatin nephrotoxicity include normal saline hydration, mannitol, and amifostine, and methotrexate-induced nephrotoxicity may be prevented with alkalinization of the urine and leucovorin rescue. Ifosfamide-induced hemorrhagic cystitis may be prevented with concomitant use of mesna.	**Case 94-9 (Questions 1, 2) Case 94-10 (Questions 1–3), Table 94-6**

CORE PRINCIPLES		CHAPTER CASES
10	Many anticancer medications demonstrate organ-specific toxicities, such as pulmonary fibrosis caused by bleomycin and transaminitis caused by cytarabine. Specific treatments for the resolution of these toxicities do not exist; rather, supportive care for symptoms is necessary. If adverse effects do not resolve, discontinuation of therapy or dose modifications may be warranted.	**Case 94-11 (Questions 1–4) Case 94-12 (Question 1), Tables 94-7, 94-8**
11	Many anticancer agents cause long-term complications after therapy, including treatment-related acute myeloid leukemia, lymphomas, bladder cancer, and bone sarcoma. The risks of secondary malignancies should be considered in assessing the adverse effect profile within the risks and benefits of specific types of therapy.	**Case 94-13 (Questions 1, 2)**
12	Cytotoxic chemotherapy is potentially gonadotoxic with the use of specific agents. Sex, age, agent, and cumulative dose are factors in determining the risk of infertility. Methods of preserving fertility should be discussed with patients before initiating therapy.	**Case 94-14 (Question 1) Case 94-15 (Questions 1–3)**

INTRODUCTION

Cytotoxic, targeted, and immune-directed anticancer agents are toxic to cancer cells and also to various host tissues and organs. Adverse effects of anticancer therapies occurring with both infusional and oral therapies can be classified as common and acute toxicities, specific organ toxicities, and long-term complications. Common and acute toxicities generally occur as a result of inhibition of host-cell division. Host tissues with renewal cell populations are most susceptible to cytotoxic agents including lymphoid tissues, bone marrow, and epithelium of the gastrointestinal (GI) tract and skin. Other common and acute toxicities (eg, hypersensitivity reactions) frequently occur in patients shortly after therapy. Specific organ toxicities often are attributed to a unique uptake or a selective toxicity of the anticancer agent to the organ. Long-term complications occur months to years after anticancer therapy and are secondary to continued immunodeficiencies or from permanent damage to organ cells from the anticancer therapy. Regardless of the type of toxicity observed, most are classified for severity by the National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events. These standardized definitions create a common method for the classification of adverse events in clinical trials and for the management of anticancer therapy administration for patients receiving standard-of-care therapies.[1] These criteria may be accessed at the NCI website (http://ctep.cancer.gov/protocolDevelopment/electronic_applications/ctc.htm).

Toxicities associated with anticancer therapies are the biggest limitation to the use of potentially curative doses. Therefore, all discussions regarding the benefits of anticancer agents must include a discussion of their associated toxicities.

Concerns regarding the toxicities of therapy include the incidence, predictability, severity, and reversibility of the adverse effects. These variables can be influenced by the specific agent, dose intensity, and treatment duration. Although predictable, the incidence and severity of adverse effects often vary depending on individual susceptibility. Distinguishing disease from the adverse effects of anticancer therapy remains challenging. Because several toxicities have well-

defined characteristics, clinicians should be aware of the most common adverse effects.

Clinicians should also be aware of patient-specific factors, such as the stage of disease, vital organ function, concomitant illnesses, and concurrent medications, which could cause signs or symptoms that mimic or contribute to the adverse effects. In addition, most patients with cancer receive many other medications, including antibiotics and analgesics, which may cause additional adverse effects or interact with anticancer agents. When a patient reports a new symptom, it may be difficult to determine whether it is secondary to anticancer therapy, concurrent medications, or disease progression. Understanding the toxicities of commonly used anticancer drugs and their management is important for optimal patient care.

COMMON AND ACUTE TOXICITIES

Hematologic Toxicities

The bone marrow contains a population of pluripotent stem cells capable of self-renewal and differentiation into any mature blood cell. Their progeny commits to either the myeloid or the lymphoid cell line. The myeloid stem cell further commits to developing into an erythrocyte (red blood cell [RBC]), megakaryocyte (platelet), or granulocyte (white blood cell [WBC]). Multiple types of granulocytes exist, including neutrophils, basophils, and eosinophils, although neutrophils are the most common type.

After committing to a particular cell line, bone marrow precursor cells undergo a series of divisions (mitosis) to increase the number of cells. The cells then undergo several developmental stages to mature and differentiate into their final forms (postmitotic) and leave the bone marrow. The total time required for a cell to pass through the mitotic and postmitotic pool under normal resting conditions is ~10 to 14 days. Although many cytokines have been identified to regulate this process, only a few growth factors are now produced

through recombinant deoxyribonucleic acid (DNA) technology for therapeutic use. These growth factors can expand the mitotic pool and accelerate maturation and differentiation, decreasing the total time spent in these stages to ~5 to 7 days.

The development and circulating life span of hematopoietic cell lines determine the severity of the depression of that cell line (nadir, lowest point) and their time course. Because RBCs survive ~120 days in the peripheral blood, clinically significant anemia is unlikely if production is impaired for a short period of time. Instead, anemia usually develops slowly after repeated courses of therapy. In contrast, platelets survive ~10 days, and granulocytes survive only 6 to 8 hours. Hence, neutropenia generally occurs before thrombocytopenia, but both may be observed after the first or subsequent courses of cytotoxic chemotherapy or targeted therapy. The clinician may have to adjust subsequent dosing based on nadir depth and time to recovery. Life-threatening neutropenia or thrombocytopenia often necessitates some action to minimize the risk of these toxicities. To mitigate these effects, one can delay therapy until recovery, reduce the dose, or administer colony-stimulating factors (CSFs, if neutropenia is of concern; or platelet transfusions, if thrombocytopenia is of concern).

MYELOSUPPRESSION

CASE 94-1

QUESTION 1: R.H., a 63-year-old, 130.07-pound (59-kg) female with no significant past medical history, presents to the university hospital with fever, night sweats, and unintended weight loss over the past 3 months. Physical examination reveals lymphadenopathy. An excisional lymph node biopsy of a cervical node reveals diffuse large B-cell lymphoma (DLBCL). Positron emission tomography (PET) scan reveals disease above and below the abdomen. R.H. is diagnosed with stage IV DLBCL. Her oncology team plans to initiate curative intent chemotherapy with rituximab 375 mg/m^2, cyclophosphamide 750 mg/m^2, doxorubicin 50 mg/m^2, vincristine 1.2 mg/m^2 on day 1 and prednisone 100 mg days 1 through 5.

Discuss the toxicities that might be expected to occur with this regimen.

What effects on the bone marrow can be anticipated and how might they clinically appear in R.H.? What factors can influence the incidence and severity of these adverse effects? When can R.H. expect these effects to occur?

This chemotherapy regimen can significantly affect any cell line, including RBCs, neutrophils, and platelets, causing significant morbidity or mortality. Decreased RBCs can cause anemia, and patients usually present with fatigue and decreased exercise tolerance. Having low neutrophil counts significantly increases a patient's risk of infections, which can be life-threatening. Moreover, reduced platelets can cause thrombocytopenia, which can increase the risk of bleeding from the GI and or genitourinary tracts as well as from the CNS.

Both patient-related and agent-related factors can significantly influence the degree of cytopenia a patient experiences after cytotoxic therapy. Agent-related factors include the specific agent, dose intensity, and dose density. Because most anticancer treatments are not given as a single agent, the effects of concurrent cytotoxic therapies may intensify the myelosuppressive effect of an individual agent. Host factors that may affect the cellularity of the bone marrow also influence the degree of cytopenia. They include the following:

1. Patient age: Younger patients are generally able to tolerate cytotoxic chemotherapy better than do elderly patients because they have a more cellular marrow with a decreased percentage of marrow fat.
2. Bone marrow reserve: Certain diseases might present with tumor cells in the bone marrow, such as leukemias and lymphomas. In these cases, the bone marrow does not have a healthy reserve of normal hematopoietic cells to help in the recovery process.
3. Previous cytotoxic chemotherapy, radiation therapy, or both: Prior cytotoxic chemotherapy and radiation therapy to fields involving marrow-producing bone (pelvic bone and sternum) reduce bone marrow reserves.

4. The ability of the liver or kidney to metabolize and excrete the compounds administered: If agents are administered to patients with specific organ insufficiencies (ie, renal or hepatic), slower clearance, resulting in increased systemic exposure, can occur. This can increase the severity and duration of cytopenias.

With most myelosuppressive agents, WBC and platelet counts begin to fall within 5 to 7 days of cytotoxic therapy administration, reach a nadir within 7 to 10 days, and recover within 14 to 26 days. Phase-specific cytotoxic chemotherapy agents, such as vinca alkaloids and antimetabolites, cause a fairly rapid onset of cytopenia that recovers faster than do those occurring with phase-nonspecific agents, such as alkylating agents and anthracyclines. Other agents that exhibit this pattern include mitomycin and mechlorethamine. All of these anticancer agents exert their cytotoxic effects during the resting phase of the cell cycle. The nitrosoureas, as well as mitomycin and mechlorethamine, can cause two neutropenic nadirs; the first nadir occurs at the conventional time expected for phase-nonspecific agents and the second nadir occurs ~4 to 6 weeks after therapy. Many combination regimens with these agents are therefore given in 6-week cycles to avoid treatment before the second nadir. However, most other myelosuppressive regimens can be safely given every 3 to 4 weeks. The majority of the targeted therapies do not suppress bone marrow production significantly, because they are designed to inhibit a specific molecular pathway or cell-surface marker rather than widely affecting rapidly proliferating cells. Because of their minimal myelosuppressive effects, targeted therapies may be desirable agents to add to regimens that are known to cause cytopenias.

Most of the agents included in R.H.’s regimen have myelosuppressive activity. Her older age may place her at higher risk for exhibiting myelosuppression. R.H. should be carefully counseled to contact her care team or report to the emergency department if she experiences signs or symptoms of an infection (including fever) or bleeding. Typically, these symptoms occur 10 to 14 days after the first day of chemotherapy.

Prevention of neutropenia

Case 94-1, Question 2: About 10 days after the first course of cytotoxic chemotherapy, R.H. experienced a fever. She was admitted to the hospital and treated with intravenous (IV) antibiotics. At the time, her WBC count was 300 cells/μL; absolute neutrophil count (ANC), 50 cells/μL; platelets, 102,000 cells/μL; and hemoglobin (Hgb), 11 g/dL. Her fever resolved after 3 days, and all culture findings were negative for bacterial growth. It is now 3 weeks after chemotherapy, and she is scheduled to receive a second course. Should she receive the same doses she was given initially?

One option would be to reduce (usually by 25%) the dose of each agent for all subsequent cycles. Although a dose reduction can clearly cause less neutropenia, reduced dose intensity can also compromise response and survival. Because R.H.'s cancer (ie, DLBCL) is both chemosensitive and potentially curable, a reduction in dosage is undesirable. To minimize the risk of neutropenia with future therapy, CSFs can be administered to R.H. to prevent potential complications associated with neutropenia.

Prophylactic administration of CSFs can be used to reduce the myelosuppressive effects of cytotoxic chemotherapy. Several CSFs —granulocyte colony-stimulating factors (G-CSFs [filgrastim, etc]), granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim]), and pegylated long-acting forms of filgrastim (pegfilgrastim, etc) are available in the United States. Pegylated filgrastim products were developed to provide the same pharmacologic benefit as filgrastim while offering the advantage and convenience of fewer injections.

Since the approval of the first CSF on the biosimilar pathway in 2015 (filgrastim-sndz), the U.S. Food and Drug Administration (FDA) has approved multiple biosimilar products for both filgrastim and pegfilgrastim. Although tbo-filgrastim was FDA approved in 2012, it is not considered a biosimilar because it was filed as a Biologics License Application, before the establishment of the FDA biologics approval pathway.

Evidence-based clinical practice guidelines for the use of CSFs have been developed by the National Comprehensive Cancer

Network (NCCN).[2] These guidelines recommend the administration of CSFs for primary prophylaxis in all patients receiving chemotherapy regimens that have been previously reported to cause a febrile neutropenia incidence of ~20%. CSF use in these patients can reduce the incidence, duration, and severity of febrile neutropenia, decrease the need for hospitalizations and broad-spectrum antibiotics, and improve the delivery of full-dose intensity chemotherapy on schedule.

Although the use of CSFs has not been shown to lead to better tumor response, it has shown a reduction in the incidence of febrile neutropenia and survival advantage. A meta-analysis of 17 randomized trials, including 3493 adult patients with solid tumors and lymphomas, showed that the use of filgrastim as primary prophylaxis reduced the risk of febrile neutropenia and improved the rate of full-dose cytotoxic chemotherapy given on schedule. In addition, the investigators in the meta-analysis observed a significant reduction in the risk of infection-related mortality and early death because of chemotherapy.[3] A systematic review of 25 randomized controlled trials (RCTs) involving over 12,000 patients confirmed this survival advantage. Compared to no-CSF support, use of CSF showed a reduction in both the relative and absolute risk of mortality. The degree of survival benefit correlated with dose intensity of chemotherapy received by the patient.[4]

The use of CSFs for secondary prophylaxis is recommended by NCCN for those patients who experience a neutropenic complication from the prior cycle, where primary CSF was not used, or when a reduced dose or treatment delay may negatively impact the survival/treatment outcome.[2] Because the regimen R.H. received does not typically produce a 20% incidence of febrile neutropenia, a CSF was not recommended for her after her first course of cytotoxic chemotherapy. Now that R.H. has experienced febrile neutropenia and she has a potentially curable malignancy, a CSF is indicated with subsequent courses of chemotherapy to prevent additional febrile episodes.

Dosing of colony-stimulating factors

Case 94-1, Question 3: How should a CSF be dosed in R.H. to reduce the severity of chemotherapy-induced neutropenia?

The recommended initial dose of G-CSF is 5 µg/kg/day as a single daily subcutaneous (SC) injection beginning 24 to 72 hours following the administration of myelotoxic chemotherapy. The dose may be rounded to the nearest vial size to improve patient convenience and reduce cost. Owing to lack of evidence, sargramostim is not recommended as a preventative CSF and is primarily reserved for stem cell mobilization before stem cell transplant.

The manufacturers recommend that therapy with filgrastim continues until the patient's neutrophil count is >10,000 cells/µL after the expected chemotherapy nadir. This is based on the observation that the neutrophil count falls roughly 50% after discontinuing a CSF. The risk of bacterial infection is highest, however, in patients with neutrophil counts of <500 to 1000 cells/µL; patients with neutrophil counts greater than that are not thought to be at high risk for bacterial infections. Thus, the national guidelines recommend continuation until post-nadir ANC has recovered to normal or near-normal laboratory standards. Many clinicians elect to discontinue the CSF when the neutrophil count reaches 2000 to 4000 cells/µL after the chemotherapy nadir to reduce the number of treatment days and cost.

Pegylated versions of filgrastim have a longer half-life, allowing for a single administration of 6 mg 24 to 72 hours after myelotoxic chemotherapy. In general, there should be at least 12 days between the dose of pegylated filgrastim and the next cycle of chemotherapy.[2] For patient convenience, a new formulation of pegfilgrastim that is a timed automated-inject device that delivers the medication 27 hours after it is activated was approved, allowing for application on the same day as chemotherapy.[5] In summary, options for R.H. include G-CSF 300 µg/day beginning the day after her last dose of chemotherapy and continuing until the ANC is >2000 to 4000 cells/

μL. Alternatively, R.H. could receive pegylated filgrastim 6-mg single injection the day after chemotherapy administration. The most common adverse effect associated with G-CSF is mild-to-moderate bone pain. Bone pain is most commonly experienced when patients begin to recover peripheral blood cells after their nadir. The proposed mechanism involves multiple factors, including inflammation and histamine release. Most patients commonly report pain in bone marrow–rich areas, such as the sternum and pelvic regions. Patients should be advised that the bone pain experienced during marrow recovery is normal. Treatment options include analgesic agents and antihistamines such as loratadine.[2]

Treatment of fever and neutropenia with a colony-stimulating factor

Case 94-1, Question 4: If R.H. was not given filgrastim and presented with febrile neutropenia, would CSF therapy be helpful?

Febrile neutropenia leads to increased hospital admissions and greater morbidity and mortality, so the optimal indication for CSFs is as prophylaxis; however, CSFs have been studied as part of the treatment of neutropenic fever. Because the duration of neutropenia is the most significant prognostic factor in patients with established febrile neutropenia, the major benefit of CSFs is their ability to reduce the duration of neutropenia.

The ability of CSFs to reduce the duration of neutropenia in patients with established febrile neutropenia has been addressed in numerous randomized, double-blind, placebo-controlled trials and two meta-analyses.[6–8] The combined data reveal minimal-to-moderate benefit in reducing hospital stays and no differences in mortality. Furthermore, questions have been raised as to whether all patients with febrile neutropenia require hospitalization. Several studies have shown equal efficacy and safety with increased cost-effectiveness of outpatient treatment of febrile neutropenia based on patient-specific risk factors.[9–11] Although CSFs do appear to hasten

neutrophil recovery, the true cost–benefit ratio associated with the use of these products in established febrile neutropenia remains to be determined. The NCCN guidelines currently do not support routine use of CSFs in patients with febrile neutropenia, although they do recognize that certain patients with febrile neutropenia and high-risk features predictive of poor outcome (eg, age older than 65 years, pneumonia, fungal infection, sepsis syndrome, anticipated >10 days of neutropenia, or prior episode(s) of febrile neutropenia) may benefit from use of CSFs.[2]

Thrombocytopenia

A reduction in platelets is another common myelosuppressive toxicity seen with chemotherapy and targeted therapies. Each chemotherapy agent differs in how it causes thrombocytopenia, and incidence and severity vary greatly depending on the treatment used. Treatment-induced thrombocytopenia is generally short lived. If needed, it is usually managed via the use of platelet transfusions and modifications to the chemotherapy dosing scheme.

Thrombopoietin is the main regulator of platelet production. There are now available thrombopoietin receptor agonists that are potent stimulators of platelet production. At this time, however, there is insufficient evidence to recommend their routine use for chemotherapy-induced thrombocytopenia.[12]

Anemia

Anemia usually is not a dose-limiting toxicity commonly associated with cytotoxic chemotherapy, because RBCs survive ~120 days. Chemotherapy predominantly affects RBCs by causing anisocytosis and macrocytosis. These effects are related to inhibition of DNA synthesis, and they predominantly occur after treatment with antimetabolites, including folic acid analogs, hydroxyurea, purine antagonists, and pyrimidine antagonists. Anemia commonly does not accompany these changes in RBC size. In addition, chemotherapy-induced effects on RBCs are rarely the sole factor contributing to the

low Hgb levels that necessitate an RBC transfusion. See Chapter 92, Anemias, for additional information on anemias and their treatment.

BLEEDING AND COAGULOPATHIES

Bleeding can occur after treatment with asparaginase or the pegylated formulation, pegaspargase, because of inhibition of the synthesis of fibrinogen and other specific coagulation factors produced by the liver under the influence of vitamin K.[13–15] Asparaginase has a widespread effect on protein synthesis, and many plasma protein factors are depressed shortly after treatment. A patient receiving asparaginase can often exhibit a depressed fibrinogen and a prolonged prothrombin time (PT) and partial thromboplastin time (PTT). This suggests that there may be a global inhibition of the production of both coagulant and anticoagulant proteins in the liver. Treatment of low fibrinogen and the prolonged PT and PTT with coagulation factors, fibrinogen, cryoprecipitate, fresh-frozen plasma, and antithrombin III remains controversial. In addition, the role of thrombosis prophylaxis in these patients has not been clearly defined.

Bleeding can also occur with the Bruton tyrosine kinase (BTK) inhibitors because of both on-target and off-target kinase inhibition. BTK, along with additional members of the SFK (src family kinases) and the TEC family are involved in several platelet activation and adhesion functions.[16] Ibrutinib, a first-generation BTK inhibitor, shows strong inhibition of BTK and TEC, and is associated with a higher risk of bleeding. Unlike ibrutinib, second-generation BTK inhibitors, acalabrutinib and zanubrutinib show a lower risk of bleeding because they do not inhibit TEC and are more specific to BTK. It is recommended to avoid the combination of warfarin and a BTK inhibitor because of the heightened risk of fatal bleeds noted in early clinical trials.[17] However, use of anticoagulation or antiplatelet therapy in patients on BTK inhibitors is not a contraindication.

Thrombotic events

The risk of venous thrombotic events is markedly elevated in patients with cancer. Trousseau first reported an increased incidence of venous thrombosis in patients with cancer, and many investigators have since confirmed this relationship.[18] Up to one-third of apparently healthy adults who exhibit otherwise unexplained deep vein thrombosis eventually are proved to have a malignancy.[19,20] Possible pathophysiologic mechanisms include hypercoagulability marked by abnormalities in clotting factors and the coagulation cascade, vessel wall damage, and vessel wall compression by tumor masses. Additional risk factors for thromboembolic events include the type and stage of cancer, comorbidities, mobility, and type of systemic anticancer therapy received, among others. Pancreatic, stomach, kidney, lung, brain, and uterine cancers are associated with the highest risk of thrombosis.[21] Several anticancer agents have been associated with an increased thrombosis risk, including, but not limited to, cytotoxic chemotherapy and hormonal agents.[22]

The immunomodulatory agents, in combination with other agents, including dexamethasone and doxorubicin, have been associated with venous thromboembolic events when used in the treatment of multiple myeloma and other diseases.[23–25] Prophylaxis is warranted when these agents are used. Guidelines address prophylaxis, including the use of aspirin, low-molecular-weight heparin (LMWH), and warfarin, for patients on immunomodulatory agents.[23,26,27] At this time, there is insufficient evidence to recommend the use of direct-acting oral anticoagulants (DOACs) for prophylaxis in those receiving immunomodulatory agents.

The vascular endothelial growth factor (VEGF) inhibitors are associated with both arterial thrombosis and bleeding events. A pooled analysis of the VEGF inhibitor bevacizumab and meta-analysis of the tyrosine kinase inhibitors (TKIs) sorafenib and sunitinib demonstrated a 3.8% and 1.4% incidence of arterial thrombosis, respectively.[28,29] Most bleeding events associated with VEGF inhibitors are minor. However, severe major bleeding events have been reported in patients with metastatic colorectal and lung cancer.[30]

Other factors can cause patients to experience thrombosis. Many patients receiving cancer therapy often undergo surgical procedures, remain immobile, and have other illnesses, such as infection, that may predispose them to developing thrombosis. Clinicians should maintain a high index of suspicion when a patient with cancer presents with signs or symptoms of thrombosis. National guidelines exist to guide treatment of thrombotic events in patients with cancer.[23] Depending on the clinical scenario, patient risk of thrombocytopenia or bleeding, and patient preference, LWMH, DOACs, and warfarin are suitable options for the management of cancer-associated thrombosis. The optimal duration of anticoagulation for cancer-associated thrombosis remains controversial. Treatment is typically continued until there is no evidence of active malignancy or if the risk of further anticoagulation outweighs the benefit.

Disseminated intravascular coagulation (DIC) occurs in many patients with acute promyelocytic leukemia (APL).[31,32] DIC is a systemic process that results from activation of the clotting cascade and presents as overlapping bleeding and thrombotic events. These events can result in end-organ damage, including intracranial hemorrhage. The lysed tumor cells in patients with APL appear to release procoagulant materials after anticancer therapy, causing both hemorrhagic and thrombotic events. The foundation of treatment for DIC is to treat the underlying disease. Use of heparin and antifibrinolytics to minimize the risk of coagulation is controversial. Other treatment is primarily supportive with blood products, including platelets and cryoprecipitate.[32]

Gastrointestinal Tract Toxicities

The GI tract may be second only to bone marrow in its susceptibility to toxic effects produced by cytotoxic chemotherapy and targeted therapies. GI toxicities include nausea and vomiting, oral complications, esophagitis, and lower bowel disturbances.

NAUSEA AND VOMITING

Nausea and vomiting are common and serious toxicities associated with many cytotoxic and targeted anticancer agents. Anticancer agents or their metabolites may stimulate dopamine or serotonin receptors in the GI tract, chemoreceptor trigger zone, or CNS, which ultimately act on the vomiting center. Emesis most commonly occurs on the first day of chemotherapy and often persists for several days thereafter.[33] Most patients who receive traditional cytotoxic chemotherapy agents require antiemetics before and after chemotherapy for several days to prevent and control these symptoms. The most appropriate antiemetic regimen is based on patient-specific and agent-specific factors. Some targeted therapy agents carry a risk of emetogenicity, although it is generally milder. Guidelines incorporate targeted agents into their emetogenic classification schema based on the incidence of nausea and vomiting in clinical trials (see Chapter 22, Nausea and Vomiting, for antiemetic algorithms and emetogenic potential of anticancer agents).

COMPLICATIONS OF THE ORAL CAVITY

Complications of the oral cavity include mucositis (or stomatitis), xerostomia (dry mouth), infection, and bleeding. The incidence of severe oral mucositis varies with the anticancer therapies given. Doxorubicin and continuous-infusion fluorouracil are among chemotherapy agents at highest risk for causing severe mucositis. Virtually all patients who receive myeloablative hematopoietic cell transplantation (HCT) or have radiation therapy to the head and neck experience oral complications.[34] These toxicities occur because of the nonspecific effects of chemotherapy and radiation on cells undergoing rapid division, including the cells of the mouth that undergo rapid renewal with a turnover time equal to 7 to 14 days. Cytotoxic therapy reduces the renewal rate of the basal epithelium and can cause mucosal atrophy, as well as glandular and collagen degeneration.[34] Radiation therapy to the head and neck causes mucosal atrophy by decreasing cell renewal, fibrosis of the salivary

glands, muscles, ligaments, and blood vessels, and damage to the taste buds.[35] Although targeted therapies are generally less toxic to normal cells, they can have substantial effects on oral tissues.[36] The current understanding of the mechanism of oral injury with targeted therapies is limited; however, clinical features of oral lesions differ from those of chemotherapy or radiation.

The combined effects of therapy on the oral mucosa can also cause infection and bleeding in the oral cavity. Because the oral mucosa is highly vascular and frequently traumatized, bleeding occurs commonly with thrombocytopenia. In addition, neutropenia can lead to oral infections by the extensive microbial flora of the oral cavity.

Oral complications often compound one another. Mucositis can clearly predispose the oral cavity to local bleeding and infection, as well as systemic infections leading to sepsis. These oral complications can also cause varying degrees of discomfort and adversely affect the patient's ability to eat, which may lead to a compromised nutritional status and an inability to continue further anticancer therapy. Treatments for the management of oral complications are reviewed extensively in guidelines.[37]

Xerostomia

CASE 94-2

Question 1: J.B. is a 55-year-old male with newly diagnosed, locally advanced head and neck cancer. His planned therapy includes cisplatin and fluorouracil given with concurrent radiation for a total of 6 weeks after surgical resection. A review of systems suggests that J.B. has poor oral hygiene, and a decision is made to consult the dental department of the university hospital before initiating radiation and chemotherapy.

Is J.B. at risk for experiencing oral complications of chemotherapy? Should anything be completed at this point to decrease his risk?

J.B. is at high risk for several of the oral complications previously described. Xerostomia, one of the most frequent side effects of radiation therapy to the head and neck, is multifactorial, mostly

occurring secondary to radiation-induced changes to the salivary glands.[38] Evidence supports a direct relationship between the radiation dose to the salivary glands and the extent of glandular changes.[39] The radiation level necessary to cause severe dysfunction to gland tissue is >52 Gray (Gy, radiation absorbed dose).[40] Below this threshold, the radiation damage to salivary glands generally has a transient and reversible duration within 6 to 12 months.

J.B. will receive a total of 50 to 70 Gy. He will also be receiving chemotherapy agents (ie, cisplatin) that can cause xerostomia and enhance the toxicity to the salivary glands.

Damage to the salivary glands causes various effects, including a loss of salivary buffering capacity, lower salivary pH, and reduction of saliva production. In addition, xerostomia can alter the sense of taste, causing some patients to lose their ability to taste or differentiate between tastes. Xerostomia also commonly causes caries. Caries and decalcification may become sufficiently severe to compromise tooth integrity and cause fracture. Because saliva is no longer available to help clear bacteria from the mouth, xerostomia also predisposes patients to oral infection.

Treatments and Prevention

Amifostine, an organic thiophosphate chemoprotection agent, is approved to reduce the incidence of moderate-to-severe xerostomia in patients having postoperative radiation treatment for head and neck cancer. Guidelines support the use of amifostine to reduce the incidence of xerostomia in patients receiving fractionated radiation therapy without concurrent chemotherapy for head and neck cancer.[41] However, amifostine is not widely used because of its cost and adverse effect profile, which includes hypotension. If xerostomia occurs, treatment strategies can include stimulation of existing salivary flow and replacement of lost secretions. Relatively low doses of systemically administered pilocarpine (5–10 mg orally three times daily) may stimulate salivary flow and produce clinically significant benefits in patients with postradiation xerostomia.[42]

Results demonstrating pilocarpine's benefit are inconsistent. Dose-related adverse effects include cholinergic effects, such as sweating, rhinitis, headache, nausea, and abdominal cramps. Cevimeline (30 mg orally three times daily) and bethanechol (25 mg orally three times daily) may have fewer side effects than does pilocarpine; however, evidence is lacking.[41] Sugarless chewing gum or candy-containing xylitol or sorbitol and saliva substitute can also be used to stimulate salivation and provide oral comfort.

Teeth should be cleaned at least twice a day and the daily use of fluoride and chlorhexidine rinses may also be useful in preventing caries. In general, a dentist should see patients who will be receiving radiation therapy to the head and neck or chemotherapy agents with a high risk of oral complications before starting therapy. This includes patients with hematologic malignancies who will most likely experience severe myelosuppression for prolonged periods. Oral evaluation before therapy with intervention to eliminate potential sources of infection or irritation and preventive measures taken during therapy can dramatically decrease the frequency of oral complications.[43,44] Given J.B.'s risk factors, including the dose of radiation he will receive and concomitant therapy with cisplatin, a dental examination is indicated before initiating therapy.

Mucositis and stomatitis

Case 94-2, Question 2: J.B. successfully completed his first 2 weeks of combined chemotherapy and radiation therapy; however, 3 days into his third week, he endorses generalized burning, discomfort, and pain on the ventral surface of his tongue. On clinical observation, both the ventral surface of his tongue and the floor of his mouth appear erythematous, and several discrete lesions are present in both areas. What is the most likely explanation for J.B.'s new onset of symptoms? What treatment is indicated at this time?

Mucositis occurs as a nonspecific effect of chemotherapy and radiation therapy on the basal epithelium of the mouth. Nonkeratinized mucosa is affected most often. Thus, the buccal, labial, and soft palate mucosa, the ventral surface of the tongue, and

the floor of the mouth are the most common sites of involvement. Although lesions are generally discrete initially, they often progress to produce large areas of ulceration. The lesions typically do not progress outside the mouth, but they may extend to the esophagus and involve the entire GI tract. Signs and symptoms generally occur about 5 to 7 days after chemotherapy or at almost any point during radiation therapy. The antimetabolites (eg, methotrexate, fluorouracil, capecitabine, and cytarabine) and the antitumor antibiotics are the chemotherapy agents that most commonly produce direct effects on the epithelial cells of the GI tract. Lesions generally regress and resolve completely in ~1 to 3 weeks, depending on their severity.

The terms stomatitis and oral mucositis may be used interchangeably. Unlike oral toxicity seen with conventional chemotherapy or radiation, aphthous-like mucositis (canker sores) or stomatitis is a prevalent toxicity distinctly seen with targeted therapies, such as mTOR (mammalian target of rapamycin) inhibitors. Lesions typically appear during the first cycle of therapy, within the first week. Other targeted therapies, such as sunitinib, regorafenib, and sorafenib, cause oral sensitivity or burning with no other clinical signs.

Treatments and Prevention

Management often consists of supportive care measures and dose reductions.[44,45]

Topical anesthetics, most commonly viscous lidocaine 2%, are often recommended. Equal portions of lidocaine, diphenhydramine, and magnesium-containing or aluminum-containing antacids can be used for their anesthetic and astringent properties. Many institutions compound mouthwash products containing these ingredients as well as nystatin or corticosteroids. Topical sucralfate is not recommended because of lack of efficacy.[45] These topical products provide symptom control only and are not effective for lesions in the lower GI tract. All the topical anesthetic-containing preparations are recommended for use as “swish and spit.” The risk of the systemic effects from topical anesthetic preparations is slim if patients were to

swallow them; however, large quantities swallowed could induce sedation and possible arrhythmias.

Gelclair® is a bioadherent oral gel containing polyvinylpyrrolidone, hyaluronic acid, and glycyrrhetinic acid (but no alcohol or anesthetic agent). It provides an adherent barrier over the mucosal surfaces, thereby shielding oral lesions from the effect of food, liquids, and saliva.[46] Controlled clinical data are lacking, and no significant differences have been found between use of Gelclair® and standard of care in relieving general pain.[47] Other palliative treatment options include topical benzocaine and ice chips. Patients may also find ice chips soothing by allowing them to melt in their mouth.

In severe cases, mucositis may require parenteral opioid analgesics for relief. Mucositis may be confused with or occur concurrently with an oral infection (particularly thrush). Under normal conditions, the mucosa provides a natural barrier to the entry of normal oral flora, but the ulcerated mucosa allows pathogens access to the bloodstream. It is important to note that patients can develop life-threatening infection or sepsis in addition to a local infection.

J.B. appears to have a mild case of stomatitis or mucositis at this time. J.B. should be encouraged to maintain good mouth care by keeping his mouth clean. In addition, topical anesthetics are indicated for J.B. Topical lidocaine or a mixture of topical lidocaine with diphenhydramine and an antacid, 5 to 10 mL swish and spit three to six times per day, should be recommended. If the lesions progress during the next several days, systemic opioids may be necessary. J.B. should also be carefully assessed for local infections within his mouth.

Case 94-2, Question 3: Could J.B.'s mucositis have been prevented?

Treatment of therapy-induced mucositis is aimed at reducing symptoms once they occur and avoiding further trauma to the oral mucosa. Guidelines recommend cryotherapy in patients receiving bolus fluorouracil and high-dose melphalan.[45,48] With cryotherapy, ice chips are placed in the mouth 5 minutes before chemotherapy

begins and retained for 30 minutes. Theoretically, this reduces blood flow to the mouth, thereby protecting the dividing cell population from toxins.

Chlorhexidine gluconate 0.12% also may reduce the frequency and severity of mucositis and infection by eliminating microorganisms in the oral cavity.[49,50] Not all studies have shown a benefit with prophylactic chlorhexidine, and its use can cause oral burning due to the product's alcohol content. Alcohol-free formulations are available and preferred. Prophylactic use of dexamethasone mouthwash significantly reduces the incidence and severity of stomatitis in patients receiving the mTOR inhibitor everolimus.[51] Because of this, topical, intralesional, or systemic steroids can be used for the management of ulcerative stomatitis due to targeted therapies.

Palifermin, a keratinocyte growth factor, is approved for patients with hematologic malignancies undergoing HCT to reduce the incidence and duration of severe oral mucositis. For further discussion, see Chapter 101, Hematopoietic Stem Cell Transplantation.

Other methods for decreasing the incidence and severity of mucositis symptoms include reducing the dose of radiation, cytotoxic, or targeted therapy, but doing so comes at the risk of compromising treatment outcomes. Mucositis remains a dose-limiting toxicity for several anticancer regimens. Unfortunately, there are no prevention strategies that would reduce the chance of J.B. experiencing mucositis from his chemotherapy and radiation, and, thus, treatment for J.B. is targeted toward relief of symptoms.

ESOPHAGITIS

Cytotoxic chemotherapy and radiation therapy can also damage the mucosal lining of the esophagus. Although dysphagia is a common symptom reported by patients with esophagitis, other causes of dysphagia should be excluded. Because patients receiving myelosuppressive therapy may exhibit infectious esophagitis, bacterial, viral, and fungal cultures should be completed to search for

infectious causes before starting treatment for esophagitis. Symptomatic management of esophagitis is similar to the management of mucositis. Other treatment modalities, including behavioral modifications (eg, elimination of acidic and irritating foods) and other medications (eg, histamine-2 [H_2] receptor antagonist, antacids, and proton-pump inhibitors), may reduce esophageal irritation and improve comfort. Patients with severe esophagitis should be carefully monitored to ensure adequate oral hydration and nutritional intake.

LOWER GASTROINTESTINAL TRACT COMPLICATIONS

Lower GI tract complications associated with anticancer therapy include malabsorption, diarrhea, and constipation. These complications may be related to structural changes that occur to the GI tract as a result of disease, after cytotoxic, targeted, or radiation therapy, graft versus host disease, and infections.

Diarrhea is common during cancer treatment and is seen with a number of cytotoxic (such as irinotecan- or fluorouracil-based regimens) and targeted therapies (such as idelalisib, ibrutinib, bosutinib, and neratinib). Unlike diarrhea, constipation is rare. The vinca alkaloids, which produce colicky abdominal pain, constipation, and adynamic ileus caused by autonomic nerve dysfunction (see the section on Neurotoxicity), can cause chemotherapy-induced constipation. Constipation should be treated prophylactically with stool softeners and mild stimulant laxatives. In addition, many medications (eg, opioid analgesics and antiemetics) and clinical conditions (eg, immobility and spinal cord compression) commonly associated with cancer and anticancer therapies can contribute to these symptoms.

Diarrhea

CASE 94-3

QUESTION 1: B.G., a 60-year-old female with recurrent colorectal cancer refractory to FOLFOX (fluorouracil, leucovorin, and oxaliplatin), is beginning her first course of cetuximab and irinotecan.

What instructions should she receive regarding the management of diarrhea if she experiences this complication?

Diarrhea is a common toxicity seen with both cytotoxic and targeted therapies; and it can cause depletion of fluids and electrolytes, malnutrition, dehydration, and hospitalization, all of which can interfere with cancer treatment and may have an impact on survival. Diarrhea is a toxicity in which patient education is paramount.

The mechanism of diarrhea is not completely understood, is likely multifactorial, and varies depending on the therapy. Diarrhea may result from direct effects on the GI mucosa, secretory factors, dysmotility, immune-related, and parasympathetic (irinotecan) effects. A review provides an excellent summary of targeted therapy–induced diarrhea.[52]

Irinotecan can cause two patterns of severe diarrhea, early and late onset, which appear to be mediated by different mechanisms. The early-onset diarrhea (within 24 hours of treatment) is cholinergic in nature and is often accompanied by other cholinergic symptoms, such as rhinitis, increased salivation, miosis, lacrimation, diaphoresis, flushing, and abdominal cramping. These symptoms can be prevented or managed with atropine. Late-onset diarrhea (generally occurring >24 hours after treatment) can be prolonged, leading to dehydration, electrolyte imbalances, and significant morbidity and is not cholinergic mediated. Late-onset diarrhea should be managed with antimotility agents, usually loperamide.[53] The maximum dose of loperamide (16 mg in 24 hours) does not apply for irinotecan-induced diarrhea. Fluid and electrolyte replacement should also be administered, if necessary. Guideline-recommended additional options for diarrhea management include diphenoxylate-atropine, the somatostatin analog, octreotide, and tincture of opium or paregoric.[54] Diphenoxylate plus atropine is used as second line or in combination with loperamide for the treatment of grade 1 or 2 diarrhea at a dosage of 1 to 2 tablets every 6 to 8 hours.

Side effects include dry mouth, blurred vision, insomnia, and dyspepsia.[55]

Evidence for octreotide for therapy-induced diarrhea is inconsistent.[56] Nevertheless, some evidence shows that octreotide may be used to successfully manage diarrhea associated with fluorouracil and other high-dose chemotherapy regimens.[56,57] Octreotide regulates intestinal fluid and electrolyte transport, increasing transit time and reducing intestinal secretions. Although responses seem to correlate with increasing octreotide dose, more studies are needed to determine the optimal dose.[58,59] Based on current evidence and the cost of octreotide, use is limited to second-line therapy for cytotoxic therapy–associated diarrhea. Other treatment options for chemotherapy-induced diarrhea, including antibiotics, opioids, and corticosteroids, have been evaluated and are summarized in review articles.[54,60]

B.G. is also to receive cetuximab, an epidermal growth factor receptor (EGFR) inhibitor in combination with irinotecan. Diarrhea is a common side effect of cetuximab when given alone or in combination therapy.[52] No specific guidelines are available to guide in the management of targeted therapy–induced diarrhea. Because a secretory mechanism represents the most frequent cause of the diarrhea with targeted agents, loperamide is the first choice for management. Certain targeted agents, such as neratinib, a human epidermal growth factor receptor 2 (HER2) TKI indicated in breast cancer, require antidiarrheal prophylaxis with loperamide at therapy initiation because of high incidence and severity of treatment-induced diarrhea.[61] The incidence and severity of diarrhea with targeted agents generally declines over time and may be dose related.[52]

Some targeted therapies and immunotherapies can cause immune-mediated diarrhea and/or colitis. Specific guidelines exist to guide management of immunotherapy-related GI toxicities, including the use of corticosteroids.[62] Other medications indicated for inflammatory bowel diseases, such as infliximab and vedolizumab, may be useful in certain circumstances. For further discussion, see the section on Immunotherapy-related toxicities.

B.G. should be counseled on the diarrhea that is seen with irinotecan. She should be instructed to call her clinic if she experiences diarrhea within 24 hours of administration of irinotecan so that she can receive prompt atropine therapy. In addition, she should be given instructions for loperamide administration and oral hydration recommendations for diarrhea occurring beyond the initial 24 hours after chemotherapy. For future cycles of therapy, atropine can be given prophylactically to prevent future occurrence of early-onset diarrhea, if it occurs.

Dermatologic Toxicities

Dermatologic toxicities associated with anticancer therapies include alopecia, rash (ranging from acneiform to toxic epidermal necrolysis), hyperpigmentation, radiation recall, photosensitivity, nail changes, hand–foot syndrome, hypersensitivity reactions, and extravasations. Several reviews serve as excellent references and provide detail related to dermatologic toxicities of targeted agents.[63–66]

ALOPECIA

CASE 94-4

Question 1: C.W. is a 45-year-old female with recently diagnosed breast cancer, who underwent lymph node dissection and lumpectomy. She will receive radiation therapy to the affected breast and chemotherapy to minimize her risk of recurrence. She is in the clinic today to receive the first of four cycles of doxorubicin and cyclophosphamide (AC). You counsel C.W. on the most common toxicities she might experience by reviewing the likelihood and management of myelosuppression, nausea, and vomiting. Her overriding concern is whether she will lose her hair.

Is C.W.'s concern typical of most patients with cancer? How would you respond?

Several investigators have reported that hair loss ranks second only to nausea and vomiting as a patient's greatest fear. Because hair

follicles replicate every 12 to 24 hours, the cells are susceptible to various cytotoxic chemotherapy agents. Normally, hair follicles independently move cyclically through phases of growth (anagen), involution or transition (catagen), and rest (telogen). Because ~85% to 90% of hair follicles are in the anagen phase, chemotherapy agents may partially or completely inhibit mitosis or impair metabolic processes in the hair matrix. These effects can cause a thinned or weakened hair shaft or failure to form hair. Hair loss usually begins 7 to 10 days after the first treatment, with prominent hair loss noted within 1 or 2 months.

Targeted anticancer therapies may cause hair thinning without complete hair loss. Other terminal hairs, such as beards, eyebrows, eyelashes, and axillary and pubic hair, can be affected; however, these effects are somewhat variable, depending on the rate of mitosis and the percentage of hairs in the anagen phase.[67,68]

C.W. should be informed about the expected onset of hair loss, and she should be reassured that alopecia caused by cytotoxic chemotherapy is reversible. She can expect her hair to begin regenerating 1 to 2 months after therapy is completed. The color and texture of her hair may be altered when it has grown back.

Several interventions have been proposed to prevent scalp hair loss during chemotherapy. These procedures attempt to prevent chemotherapy agents from circulating to the hair follicles with either an occlusive scalp tourniquet or a cooling cap that produces a localized hypothermia and vasoconstriction. The Paxman™ Scalp Cooling System is an FDA-approved product for patients with solid tumors to reduce chemotherapy-related hair loss. It has demonstrated variable efficacy in hair retention during chemotherapy.[69] Recognizing that such devices create a refuge for tumor cells, these procedures are contraindicated in patients with hematologic malignancies and in others at risk for CNS metastases. Concerns regarding the safety of these devices have slowed widespread uptake in the U.S. market.[70,71] Topical minoxidil has been studied with unimpressive results to date.[71]

C.W. is likely to experience near or complete hair loss, depending on the thickness of her hair and its growth rate. She should be

educated on options to minimize the effect of alopecia on her appearance, if desired, through the use of hair pieces or stylish head wraps.

CASE 94-4, QUESTION 2: Besides alopecia, what other skin or nail changes should C.W. anticipate?

NAIL AND SKIN CHANGES

Several skin and nail changes have been associated with cytotoxic and targeted anticancer agents. The major consequences of these toxicities are cosmetic, generally resolving within 6 to 12 months of discontinuing or completing therapy.

Nail changes

The growth of fingernails and toenails is arrested in a manner similar to hair growth. Chemotherapy has been associated with various types of nail changes such as nail dystrophy, different patterns of nail discoloration (known as chromonychia), leukonychia, Beau lines, paronychia, and hemorrhagic onycholysis. Nail changes are most common in patients receiving paclitaxel and docetaxel but have occurred after therapy with cyclophosphamide, fluorouracil, daunorubicin, doxorubicin, and bleomycin.[63,72–74] Nail changes as a result of chemotherapy are asymptomatic and resolve with the cessation of therapy. They are observed more commonly in patients with more pigmented skin color.

Dermatologic pigment changes

Dermatologic pigment changes are common with chemotherapy and targeted therapies. The mechanisms behind these changes are not well understood. Hyperpigmentation is most frequently reported, with hypopigmentation occurring rarely. Hyperpigmentation is seen with a wide variety of cytotoxic agents, including anthracyclines, alkylating agents, and antimetabolites. Most agents cause a diffuse, generalized hyperpigmentation, but the pigmentation changes can

also be localized, involving only the mucous membrane, hair, or nails.

Rare reactions are noted in hair. Methotrexate can cause hyperpigmented banding of light-colored hair. Alternatively, depigmentation of hair has been seen with several TKIs including sunitinib, imatinib, cabozantinib, sorafenib, and pazopanib. This adverse effect is attributed to c-KIT signal inhibition, leading to decreased melanin synthesis.[75]

As previously stated, pigment changes that occur in patients receiving cytotoxic chemotherapy are a cosmetic concern. It is important to anticipate these distressing side effects and educate patients. At this time, C.W. should receive counseling, explaining that these side effects may occur, but are purely cosmetic. She should be reassured that pigment changes usually resolve with time.

Hand–foot syndrome

Patients receiving chemotherapy or targeted agents may exhibit tender, erythematous skin on the palms of their hands and sometimes on the soles of their feet. Tingling and numbness can also be reported. In the most severe form, the lesions can progress to bullous lesions that desquamate. The condition generally resolves over 2 to 4 weeks; however, it may recur with increasing severity in response to repeated treatment.[76] This reaction is also referred to as *acral erythema* or *palmar–plantar erythrodysesthesia*.

The pathogenesis of hand–foot syndrome is poorly understood, and it is hypothesized to be different for each class of drug. Agents most commonly reported to cause this reaction include cytarabine, fluorouracil, doxorubicin, liposomal doxorubicin, docetaxel, capecitabine, sorafenib, sunitinib, pazopanib, regorafenib, axitinib, and vemurafenib.[77,78]

Prophylactic use of 10% urea-based cream three times daily for 6 to 12 weeks has shown to reduce the incidence of hand–foot syndrome compared to best supportive care in patients receiving capecitabine and sorafenib.[79,80] Treatment is primarily focused on symptom control, and discontinuation of the medication or treatment

interruption will help resolve the reaction. After resolution, the medication may be initiated at a lower dose.

Acneiform–erythematous rash

TKIs, such as erlotinib and osimertinib, target the intracellular domain of the EGFR, and cetuximab and panitumumab are monoclonal antibodies that target the extracellular domain of EGFR. These agents are associated with skin toxicities. The most common cutaneous side effect is a dose-dependent acneiform eruption on the face, scalp, chest, and upper back due to inhibition of EGFR found in keratinocytes in the skin. The rash generally develops in the first 1 to 2 weeks of treatment, peaks at 3 to 4 weeks on therapy, and its intensity decreases after 2 weeks but can often persist over some months. Although the rash can be cosmetically distressing, it is usually low grade and may be associated with dry skin and itching. Complete resolution without sequelae occurs once the drug is discontinued.[65,81]

Evidence suggests that the severity of the EGFR inhibitor skin rash is associated with increased efficacy. In an analysis of patients with lung cancer receiving erlotinib, those who experienced a rash had a significantly longer survival time than those who did not.[82] Higher severity rash was associated with longer survival when compared to lower severity or no rash. Evidence of a correlation between skin rashes and higher response rates has also been observed in patients receiving cetuximab for colorectal cancer.[83]

Preventative strategies include patient education to minimize sun exposure and to keep the rash moist with lotions and creams, avoiding drying agents.[84,85] The Multinational Association of Supportive Care in Cancer (MASCC) developed an EGFR Inhibitor Skin Toxicity Tool to assist clinicians in monitoring and reporting EGFR-induced dermatologic toxicities. In addition, MASCC has published both patient information and clinical practice guidelines for the prevention and treatment of EGFR inhibitor–associated dermatologic toxicities. Treatment depends on the severity and percentage of body surface area impacted. Treatment modalities

include hydrocortisone cream, clindamycin gel, and oral minocycline or doxycycline therapy.[85]

INTERACTIONS WITH RADIATION THERAPY

CASE 94-4, QUESTION 3: C.W. recently completed her course of total breast radiation therapy. She plans to leave for a 1-week vacation in Florida 3 days after this clinic visit. Are there any interactions between radiation therapy and sunlight exposure with cytotoxic anticancer agents? Are there any specific precautions that C.W. should take, or signs and symptoms of toxicity that she should know about?

Interactions between cytotoxic therapy and radiation therapy or ultraviolet (UV) light can be divided into radiation sensitization, radiation recall, photosensitivity reactions, and sunburn reactivation. Several excellent reviews that describe each of these interactions in detail are available.[86–88]

Radiation-induced cell damage leads to inflammation and chronic oxidative stress. This can cause changes in various cytokines, cell cycle changes, and DNA damage. Cytotoxic therapies interfere with enzymes and synthetic mechanisms needed to repair damaged cells, leading to a synergistic effect with radiation. Although these synergistic effects are often exploited therapeutically for the treatment of solid tumors, these reactions can inadvertently cause undesirable reactions in nontumor tissues, such as the skin, esophagus, lung, and GI tract. The skin is the most common target of radiation reactions.

Targeted therapies block specific molecular pathways, and preclinical evidence suggests many are radiosensitizing. At this time, there is little clinical data to guide the safety and efficacy of combination targeted therapies and radiation. Single institutional case series have provided mixed data, with some suggesting safety and others suggesting unexpected toxicities.[89,90] Many ongoing trials are examining the utility of combination targeted therapies and radiation.

These reactions may be further classified as either radiation sensitivity or radiation-recall reactions. Generally, sensitivity reactions occur when chemotherapy is given concurrently or within 1 week of radiation therapy. In comparison, recall reactions occur several weeks to years after radiation therapy, when the administration of chemotherapy induces an inflammatory reaction in tissues previously treated with radiation. Not surprisingly, the chemotherapy agents that have been associated with radiation-recall reactions are the same as those that cause radiation sensitivity reactions. Management of reactions is supportive and consists primarily of topical agents including corticosteroids.[86,91–93]

Because UV light has sufficient energy to cause photochemical changes in biologic molecules, cytotoxic and targeted agents can interact with it. The subsequent reactions are usually less severe than are reactions that occur with radiation therapy, and they may be caused by a different mechanism.

C.W. received doxorubicin, which can interact with radiation therapy. She should be advised to avoid direct exposure to sunlight for several days to a week after chemotherapy and to use a protective sunscreen with a high sun protective factor when she cannot avoid sun exposure.

Case 94-4, Question 4: How will C.W. know whether she has a radiation reaction? How should she be treated if such a reaction occurs?

If C.W. has a radiation reaction, she will experience “easy burning” and erythema or redness, followed by dry desquamation. With a more severe reaction, small blisters (vesicles) and oozing can develop. Necrosis with persistent painful ulceration has been reported. Postinflammatory hyperpigmentation or depigmentation may follow. Treatment options vary, depending on reaction severity, and range from topical steroids in an emollient cream to surgical debridement if necrosis and ulcers are present. Radiation reactions that occur in tissues other than on the skin (eg, the lungs, esophagus, or GI tract) often are treated with oral corticosteroids,

although data regarding the efficacy of these agents in ameliorating the symptoms or reducing the extent of damage are lacking. If C.W. experiences any of these signs or symptoms, she should immediately seek medical attention.

IRRITANT AND VESICANT REACTIONS

Case 94-4, Question 5: C.W. reported pain and burning at the injection site immediately after the administration of her third course of IV chemotherapy with doxorubicin and cyclophosphamide. She described the sensation as being distinctly different from the mild discomfort she had experienced with previous courses. Physical examination of the injection site revealed mild erythema and slight induration. What types of local reactions can occur after the administration of chemotherapy?

Several distinct types of local reactions (ranging from transient local irritation to severe tissue necrosis of the skin, surrounding vasculature, and supporting structures) have been reported after cytotoxic chemotherapy.[64,94,95] Some reactions are characterized by immediate local burning, itching, and erythema. Patients may also experience a "flare" reaction along the length of the vein used for treatment. Extravasation, a potentially serious local reaction, is seen in ~1% of chemotherapy administration and occurs when IV medications are accidentally administered into the surrounding tissue, either by leakage or by a needle puncturing the vein. The agent that extravasates causing a reaction is subclassified as a vesicant or an irritant (**Table 94-1**).

Table 94-1
Chemotherapeutic Drugs Reported to Produce Local Toxicities

Vesicants	
Dactinomycin[b]	Doxorubicin and vincristine as a continuous infusion[b]
Daunorubicin[b,c]	Epirubicin[b,c]
Doxorubicin[b,c]	Vinblastine[a,d]
Idarubicin[b,c]	Vincristine[a,d]

Vesicants	
Mechlorethamine[b,e]	Vinorelbine[a,d]
Mitomycin[b]	Trabectedin[a,d]
Irritants With Vesicant-Like Properties	
Bendamustine[b,e]	Mitoxantrone[b]
Cisplatin[b,e]	Oxaliplatin[a,e]
Melphalan	Paclitaxel[b]
Irritants	
Ado-trastuzumab[b]	Liposomal doxorubicin[b]
Arsenic trioxide[b]	Etoposide[a,d]
Albumin-bound paclitaxel[b]	Fluorouracil[b]
Brentuximab vedotin[a]	Gemcitabine
Busulfan[b]	Ifosfamide[b,f]
Cabazitaxel[b]	Irinotecan[b]
Carboplatin[b]	Streptozocin[b]
Docetaxel[b]	Liposomal daunorubicin and cytarabine (vyxeos)[b]
Dacarbazine[b]	Teniposide[a,d]

Antidote and local care: [a]topical heat, [b]topical cooling, [c]dexrazoxane, [d]hyaluronidase, [e]sodium thiosulfate, [f]topical dimethyl sulfoxide (DMSO).

Extravasation of chemotherapeutic agents: prevention and treatment. *Semin Oncol*. 2006;33(1):139–143. doi:10.1053/j.seminoncol.2005.11.007; Totect (dexrazoxane injection). Package insert. Topo Target USA, Inc.; 2011.

Vesicants can cause tissue necrosis, whereas irritants induce inflammation without direct cytotoxic injury. Some drugs may have conflicting information of being classified as a vesicant or as an irritant. Other agents can be classified as irritants with vesicant-like properties at stronger concentrations and/or larger volumes of

extravasation. In general, most targeted and immunotherapy agents are considered nonirritants and nonvesicants.

Among the multiple risk factors for extravasation, the most commonly encountered include generalized vascular disease found in elderly and debilitated patients or in patients who have undergone frequent venipuncture and treatment with irritating chemotherapy (the latter causes venous fragility and instability or decreased local blood flow).[64,94] These risks have led to the increased use of central catheters in patients receiving vesicant chemotherapy.

Case 94-4, Question 6: C.W.'s oncology nurse believes that the doxorubicin may have extravasated during administration. How should this be managed? Do management strategies differ for other vesicant agents?

Details of management of a potential irritant, an irritant with vesicant-like properties, or vesicant extravasation can be found in **Table 94-2**.

Table 94-2
Management of Suspected Extravasation

1. Stop the infusion immediately, but do not remove the needle. Do not flush the extravasated catheter.
2. Disconnect the IV tubing from the catheter. Aspirate any drug remaining in the tubing or needle, as well as the infiltrated area using a small syringe.
3. Contact medical team as soon as possible.
4. If peripheral IV, remove the IV catheter, avoid pressure to site of extravasation. Mark area of induration or swelling.
5. If deemed appropriate, instill an antidote in the infiltrated areas. Apply topical heat or cooling if indicated and elevate the extremity for the first 24–48 hours.
6. Document the drug, suspected volume extravasated, and the treatment in the patient's medical record.
7. Check the site frequently for 5–7 days.
8. Consult a surgeon familiar with extravasations depending on severity and agent extravasated so that the surgeon can periodically review the site, and, if ulceration begins, the surgeon can rapidly assess if surgical debridement or excision is necessary.

IV, intravenous.

Sources: Doellman D, Hadaway L, Bowe-Geddes LA, et al. Infiltration and extravasation: update on prevention and management. *J Infus Nurs*. 2009;32:203–211. doi:10.1097/NAN.0b013e3181aac042; Boulanger J, Ducharme A, Dufour A, et al. Management of the extravasation of antineoplastic agents. *Support Care Cancer*. 2015;23(5):1459–1471. doi:10.1007/s00520-015-2635-7.

Recommended measures aim to minimize tissue exposure and prevent subsequent tissue damage.[95] Cold compresses have been shown to cause vasoconstriction, which can help localize the extravasation and allow time for local vessels to displace the extravasated agent, whereas warm compresses are thought to induce vasodilation and increase drug distribution and absorption, thereby decreasing the concentration of the offending agent around the immediate site.

Specific antidotes thought to inactivate the extravasated chemotherapy have been suggested.[94,95] Dexrazoxane, an iron chelator, is approved for the treatment of anthracycline extravasations based on evidence that demonstrated avoidance of surgical intervention and therapy continuation without delays.[96,97]

HYPERSENSITIVITY REACTIONS

Various types of hypersensitivity reactions can occur with anticancer agents, although type I is the most common reaction documented. Type I hypersensitivity reactions are immediate reactions that are most often immunologically mediated and occurring when an antigen interacts with IgE bound to a mast cell membrane, causing degranulation of mast cells. Major signs and symptoms include urticaria, angioedema, rash, bronchospasm, abdominal cramping, and hypotension. Other mechanisms causing type I reactions include degranulation of mast cells and basophils through a direct effect on the cell surface that releases histamine and other vasoactive substances. When non–IgE-mediated mechanisms account for the symptoms of a type I reaction, it is called an *anaphylactoid reaction* (see Chapter 32, Drug Hypersensitivity Reactions). Many of the type I hypersensitivity reactions produced by anticancer medications appear to be mediated by non-IgE mechanisms, occurring during or immediately after administration of the first dose. This is in contrast

to immunologic reactions that require prior exposure (ie, one must be sensitized before becoming hypersensitized).

Although the spectrum of symptoms and their severity vary widely, most hypersensitivity reactions that occur with anticancer agents are classified as grade 1 (transient rash, mild) or grade 2 (mild bronchospasm, moderate).[1] Furthermore, a patient who has had a reaction to an agent that is not immunologically mediated can safely receive future courses of the anticancer therapy with appropriate premedication. The other types of hypersensitivity reactions with cytotoxic and targeted therapy administration are less commonly documented. Several reviews detail anticancer agents most frequently reported to produce hypersensitivity reactions and their characteristic reactions.[98–100]

Premedication can help prevent or reduce the severity of the hypersensitivity reaction. Antihistamines and acetaminophen, with or without glucocorticoids, are recommended for prophylaxis when administering certain agents that are associated with a high incidence of infusion reactions (eg, rituximab, obinutuzumab, daratumumab, alemtuzumab, and cetuximab). However, they are not completely effective, and patients must be monitored closely during and immediately following all infusions. If a patient experiences a hypersensitivity reaction and the clinician decides to continue therapy with this regimen, a full review of all of the relevant literature is advised. In addition to increased premedication to limit the risk of a subsequent reaction, successful desensitizations have been utilized and published for a few chemotherapeutic agents.[101–103]

Monoclonal antibodies

CASE 94-5

Question 1: S.R. is a 58-year-old male with metastatic relapsed colorectal cancer who will be starting cetuximab (400 mg/m^2 IV load, followed by 250 mg/m^2 IV weekly).

Discuss the toxicities that S.R. may expect and when they might appear.

How should these side effects be managed? Could these side effects be prevented?.

The most common toxicities observed in patients receiving cetuximab include rash, diarrhea, hypomagnesemia, and headache; and hypersensitivity reactions occur in 15% to 20% of patients receiving their first infusion. However, severe hypersensitivity reactions (including allergic and anaphylactic reactions) occur in 1% to 3% of patients. The reactions generally occur during or within 1 hour of completing the first dose. Patients should be premedicated with diphenhydramine before the infusion. The infusion can be stopped or the rate decreased if S.R. begins experiencing these effects. The skin rash and dry skin occurring after cetuximab administration are related to the inhibition of EGFR. Management of EGFR inhibitor–related rash has been discussed previously (see sections on Nail and Skin Changes and Acneiform–Erythematous Rash).

Monoclonal antibodies are associated with a higher incidence of hypersensitivity reactions than are traditional cytotoxic agents. These agents are genetically engineered humanized monoclonal antibodies containing foreign proteins that can trigger the reaction. The risk of a hypersensitivity reaction is highest with the first or second infusion, and usually does not recur with subsequent infusions, although this is dependent on the specific agent.[104] In general, the likelihood of an infusion reaction declines with each subsequent course of therapy.

Several monoclonal antibodies are now available in SC formulations (trastuzumab and hyaluronidase-oysk, pertuzumab and trastuzumab and hyaluronidase-zzxf, rituximab and hyaluronidase human, daratumumab, and hyaluronidase-fihj). The coformulation with recombinant human hyaluronidase increases the permeability of the SC tissue, allowing for a larger volume to be administered. SC administration of monoclonal antibodies is less time consuming (given over 3–5 minutes), and generally shows lower rates of hypersensitivity reactions compared with the IV originator product. Hypersensitivity reactions occurring with SC monoclonal antibodies

tend to be more delayed.[105] Management of hypersensitivity reactions follows the same treatment principles as with IV agents.

Treatment

Recommended treatment of hypersensitivity reactions is reviewed in **Table 94-3**. If the reaction is mild or moderate, the patient may continue with the same therapy if treatment is preceded by methods to prevent or minimize hypersensitivity reactions. It is important to note that other chemicals present in the formulation or other agents administered concomitantly with the chemotherapy can cause hypersensitivity reactions. Potential allergens included in the diluent or formulation of chemotherapy agents include Cremophor EL® (present in paclitaxel), polysorbate 80 (present in docetaxel and etoposide), benzyl alcohol (present in the parenteral form of methotrexate, cytarabine, and etoposide), and methoxypolyethylene glycol (present in liposomal doxorubicin).

Table 94-3

Treatment of Hypersensitivity Reactions From Anticancer Drugs

Treatment
Discontinue the drug immediately and contact the medical team.
Start IV of 0.9% NaCl and initiate vital signs and O_2 saturations; place the patient in recumbent position if BP is decreased; administer oxygen if O_2 saturation <90% and titrate to keep O_2 saturation >90%.
Determine whether the reaction is nonanaphylaxis (symptoms include itching, flushing, hives, mild respiratory symptoms without airway compromise) or anaphylaxis (symptoms include acute onset, rapidly progressing hives, potential airway compromise with shortness of breath, stridor, wheezing, bronchospasm, supplemental oxygen required, and/or hypotension).
If Nonanaphylaxis-Type Reaction:
Administer diphenhydramine 50 mg IV.
Administer famotidine 20 mg IV.
If symptoms progress: administer hydrocortisone 100 mg IV.
If Anaphylaxis:

Treatment
Administer epinephrine 0.3 mg IM or SC every 5 minutes until the reaction subsides.
Diphenhydramine 50 mg IV
Hydrocortisone 100 mg IV
Famotidine 20 mg IV
If wheezing that does not respond to epinephrine is present, administer nebulized albuterol solution.

BP, blood pressure; IM, intramuscular; IV, intravenous; O_2, oxygen; SC, subcutaneous.

To reduce the hypersensitivity reactions observed with paclitaxel, paclitaxel protein-bound particles (Abraxane®), an albumin-bound formulation of paclitaxel, have been created. Because paclitaxel protein-bound particle formulation is Cremophor EL® free and less likely to cause hypersensitivity than is traditional paclitaxel, it is not necessary to premedicate patients with steroids and antihistamines. Doses between the two agents are not equivalent. Although fewer hypersensitivity reactions are associated with this formulation, myelosuppression remains a dose-limiting toxicity.[106,107]

Immunotherapy-Related Toxicities

CAR-T Cell Therapy and Blinatumomab

Cytokine release syndrome

CAR-T immunotherapies are genetically engineered autologous products that target specific tumor antigens created using a patient's own T cells. CAR-T cells are designed to recognize and direct an immune response against targeted cells displaying a specific antigen. All currently available products target CD19, which is a B-cell antigen found on the surface of B cells, and have indications for non-Hodgkin lymphoma in adults (axicabtagene ciloleucel and

tisagenlecleucel), acute lymphoblastic leukemia (ALL) in pediatric patients (tisagenlecleucel) and mantle cell lymphoma in adults (brexucabtagene autoleucel). Blinatumomab, approved for ALL, is a bispecific T-cell engager (BiTE) that works to selectively direct the immune system to act against tumor cells by forming a link between T cells and tumor cells. There are many CAR-T cells and BiTE products currently in development across both solid and hematologic cancers.

Cytokine release syndrome (CRS), a systemic inflammatory condition with excessive cytokine production, may occur as a result of treatment with CAR-T therapies and blinatumomab, for which a boxed warning is applied, as well as with HCT, and other immunotherapies.[108] Severity may vary. Signs and symptoms include fever, headache, nausea, weakness, hypotension, hypoxia, tachycardia, DIC, and hepatic, renal, and cardiac dysfunction. CRS may occur concurrently or independently of neurotoxicity. The incidence of CRS was 79% to 94% of patients in clinical trials of CAR-T cells, with a subset of these being grade 3 or higher in severity (13%–49%). See **Table 94-4** for information on grading of CRS. The median onset of CRS symptoms is 2 to 3 days, with a median duration of 7 to 10 days.[109–111] Blinatumomab is associated with CRS in up to 15% of patients, with symptoms appearing around 2 days into the infusion and resolving after about 5 days.

Table 94-4
Grading of Cytokine Release Syndrome

Grade 1	Symptoms require symptomatic treatment only; consider antibiotics if neutropenic.	Fever, nausea, headache, myalgia, malaise
Grade 2	Symptoms require and respond to moderate intervention.	Oxygen requirement <40% Fio_2, or hypotension responsive to fluids or low dose of one vasopressor, or grade 2 organ toxicity
Grade 3	Symptoms require and respond to aggressive	Oxygen requirement ≥40% Fio_2, or

	intervention.	hypotension requiring high-dose or multiple vasopressors, or grade 3 organ toxicity, or grade 4 transaminitis
Grade 4	Life-threatening symptoms	Requirements for ventilator support, renal replacement therapy, or grade 4 organ toxicity other than transaminitis

Fio_2, fraction of inspired oxygen.

Without management, CRS can be life-threatening. For blinatumomab, management of CRS includes interruption of the infusion and administration of IV dexamethasone. Corticosteroids are utilized because of their immune-suppressive effects, including downregulation of the systemic cytokine response. Upon resolution, the infusion may be resumed at a reduced dose, with future dose escalation if tolerated. For grade 4 CRS, dexamethasone should be administered, and blinatumomab should be discontinued permanently.

Management of CRS related to CAR-T cell therapies depends on the severity of symptoms. In general, mild symptoms (fever, nausea, headache, myalgia, and malaise) should be managed with supportive care modalities. Antibiotics should be considered if the patient is neutropenic. For more severe CRS, the IL-6 receptor antagonist tocilizumab should be administered. IL-6 is frequently elevated during CRS, making tocilizumab an effective treatment option. It is important to recognize that corticosteroids are typically avoided for lower grade CRS, because they may have a detrimental effect on the infused CAR-T cells, leading to reduced toxicity but at the expense of efficacy. Corticosteroids may be indicated for severe or persistent CRS. Product information should be carefully reviewed for specific information on the management of CRS because there are several differences between the agents.

Neurotoxicity

CAR-T products may cause severe or life-threatening neurotoxicity, often called CAR-T-cell–related encephalopathy syndrome (CRES).[109–112] Symptoms are wide-ranging in type and severity, and include headache, encephalopathy, delirium, anxiety, dizziness, tremor, peripheral neuropathy, seizure, and aphasia. Any grade neurotoxicity occurs in about 80% of patients and ≥grade 3 in about one-third, although rates are variable among products. The median time to onset of neurotoxicity is 4 to 6 days after infusion, and the median duration of symptoms ranges from 6 to 21 days. Importantly, encephalopathy may persist for weeks to months. Patients should not drive during the 8 weeks following administration and should remain within close proximity to the hospital or clinic for at least 28 days. Initial management of neurotoxicity depends on the severity of presentation and includes consideration of seizure prophylaxis (eg, levetiracetam), and IV corticosteroids (dexamethasone or high-dose methylprednisolone). Tocilizumab is typically administered for neurotoxicity with concomitant CRS. Product-specific literature should be consulted. Risk Evaluation and Mitigation Strategy (REMS) programs are in place for all CAR-T products because of the potential for serious toxicities, and it is important that patients are educated on the risks.

IMMUNE CHECKPOINT INHIBITORS

Immune checkpoint inhibitors (ICIs) are increasingly common in the treatment of many cancer types. Currently available agents include the cytotoxic T-lymphocyte antigen 4 (CTLA-4) inhibitor (ipilimumab), programmed cell death 1(PD-1) antibodies (nivolumab, pembrolizumab, cemiplimab), and programmed death-ligand 1 (PD-L1) antibodies (atezolizumab, avelumab, durvalumab). Checkpoint proteins, such as PD-L1 on tumor cells and PD-1 on T cells, help keep the immune response in check. Blocking the binding of PD-L1 to PD-1 with an ICI allows the T cells to kill tumor cells.

Toxicities caused by ICIs are largely distinct from those associated with cytotoxic chemotherapy. ICIs cause autoimmune-like toxicities, known as immune-related adverse events (IrAEs). These toxicities

differ depending on the agent, malignancy, and individual susceptibilities. Although the skin and colon are most commonly involved, any organ may be affected, including the liver, lungs, kidneys, and heart. It is important to have a high early suspicion for toxicity related to ICIs in patients presenting with new or worsening symptoms, and to involve specialists such as dermatologists, pulmonologists, and gastroenterologists early in the patient's course.

Corticosteroids are commonly used for treatment of moderate and severe IrAEs, although additional immunosuppressive therapy may occasionally be required depending on the organ impacted.

Dermatologic toxicities

Dermatologic toxicities occur in 30% to 50% of patients on ICIs and are wide-ranging, but often include rash and pruritus. The rash may present in various ways, including erythema, lichenoid, eczematous, or psoriasis-like, among others. For mild rash, topical emollients, topical corticosteroids, and oral antihistamines are indicated. Moderate-to-severe presentations may require the use of systemic corticosteroids, and the ICI may be held or permanently discontinued. Severe cases may require hospitalization for IV hydration, electrolyte repletion, and wound care.

Pulmonary toxicities

Pulmonary toxicity associated with ICI therapy often manifests as pneumonitis, which occurs in <10% of patients, perhaps as low as about 3%. Symptoms include dyspnea, cough, fever, and chest pain. Imaging reveals ground-glass opacities or patchy nodular infiltrates that may appear distinct from other types of anticancer therapy–induced pneumonitis. Importantly, infectious etiologies should be evaluated concomitantly. ICI therapy is interrupted for radiographic evidence of pneumonitis. Grade 2 or greater warrants administration of systemic steroids, and grades 3 to 4 toxicity not responsive to steroids may require additional immune-modulating agents including infliximab, mycophenolate mofetil, intravenous immunoglobulin (IVIG), or cyclophosphamide.

Gastrointestinal toxicities

CASE 94-6

QUESTION 1: A.B. is a 51-year-old male with newly diagnosed metastatic (stage IV) non–small-cell lung cancer (NSCLC). The tumor highly expresses PD-L1. He began first-line therapy with pembrolizumab 200 mg IV once every 3 weeks. Before the fourth cycle, A.B. has new, frequent diarrhea (about five stools per day compared with baseline), with abdominal pain and occasional blood in the stool. Symptoms are consistent with grade 2 colitis, and pembrolizumab is held.

What pharmacologic treatment is indicated for A.B. at this time?

Lower GI toxicity occurs more commonly with anti-CTLA4 inhibitor (ipilimumab) (up to 54%) and also with anti-PD1 monotherapy (up to 19%). Signs and symptoms may include diarrhea only, or colitis symptoms such as mucus in the stool, abdominal pain, fever, and rectal bleeding. Clinical presentation and diagnostic findings are often consistent with inflammatory bowel disease. For patients with mild diarrhea, observation and ensuring adequate hydration are warranted. More severe symptoms, including those consistent with colitis, may require the use of systemic corticosteroids, infliximab, or vedolizumab, in addition to holding the ICI. Grade 4 toxicity warrants permanent discontinuation.

A.B. should initially receive steroids, such as prednisone 1 mg/kg/day, for the management of immunotherapy-related colitis. A.B. should also be counseled regarding dietary modifications that may help improve symptoms.

Various other organs and organ systems are affected by ICIs, including the endocrine system (hypo- and hyperthyroidism, adrenal insufficiency, and diabetes), rheumatologic, renal, neurologic, hematologic, cardiovascular, and ocular toxicities. Guidelines should be consulted for expert, multidisciplinary consensus on treatment.[62,113,114]

Specific Organ Toxicities

Nervous System

CASE 94-7

QUESTION 1: A.L., a 39-year-old female with acute lymphocytic leukemia, has been admitted to the hospital for induction chemotherapy. Methotrexate 3 g/m^2 IV once on day 1, cytarabine 2 g/m^2 IV every 12 hours on days 2 and 3 for four doses, vincristine 2 mg IV on days 1 and 8 for two doses, and dexamethasone 20 mg orally daily on days 1 through 5 are ordered. Laboratory data obtained on admission include a WBC count of 120,000 cells/μL with 9% neutrophils, 11% lymphocytes, and 80% blasts. On day 3, A.L. is confused, and she has difficulty performing a finger-to-nose neurologic examination. On day 10, she endorses numbness in her hands and feet. In addition, the clinician notes an eyelid lag and ataxia. A.L. also reports severe constipation.

What signs and symptoms of neurotoxicity is A.L. experiencing? Should the leukemia regimen be modified for future courses?

Methotrexate causes little or no neurotoxicity when administered orally or via IV in doses <1 g/m^2; however, high-dose IV methotrexate (usually >1 g/m^2) can cause acute encephalopathy. The encephalopathy that occurs after therapy with methotrexate is usually transient and reversible. Some patients may experience a progressive leukoencephalopathy after high-dose IV methotrexate. The risk of leukoencephalopathy increases with higher cumulative doses of methotrexate and concomitant cranial radiation therapy.[115,116] Chemical meningitis can occur with intrathecal administration of methotrexate and, less frequently, myelopathy or paraplegia may be observed[117] (see Chapter 95, Pediatric Malignancies). Transient stroke-like symptoms with concomitant abnormal findings on magnetic resonance imaging (MRI) have been observed in patients receiving intrathecal and IV methotrexate.[118,119]

Ifosfamide is associated with an encephalopathy thought to result from one of its metabolites, chloroacetaldehyde. The incidence ranges from 10% to 20%; it presents hours to days after initiation of treatment with confusion and disorientation, and is generally self-limiting, although coma and death have been reported. Methylene blue, albumin, and thiamine have been used for both prevention and treatment. Conclusive evidence to promote routine prophylaxis is not available.[120–122]

High doses of cytarabine (>1 g/m^2 in multiple doses) are associated with CNS toxicity in 8% to 37% of patients.[123,124] These neurotoxicities are dose and schedule related. Doses >18 g/m^2 per course increase the frequency of neurotoxicity. Older patients are more susceptible than are younger patients, and impaired renal function appears to be an inciting factor of cytarabine neurotoxicity, likely as a result of accumulation of a neurotoxic metabolite.[125] As illustrated by A.L., neurotoxicity may become evident within a few days of treatment with cytarabine, and is manifested by a generalized encephalopathy with symptoms such as confusion, obtundation, seizures, and coma. Cerebellar dysfunction, presenting as ataxia, gait and coordination difficulties, and dysmetria (inability to arrest muscular movement when desired and lack of harmonious action between muscles when executing voluntary movement), is also commonly observed. These neurologic symptoms may partially resolve over days to weeks after discontinuation of therapy. Intrathecal administration of cytarabine may cause a chemical meningitis or arachnoiditis.[117,126,127] Leukoencephalopathy typically presents with progressive personality and intellectual decline, dementia, hemiparesis and, rarely, seizures.

Fludarabine can cause severe neurotoxicity when used at doses >90 mg/m^2 for 5 to 7 days.[128–130] Symptoms include altered mental status, photophobia, amaurosis (blindness that usually is temporary without change in the eye itself), generalized seizures, spastic or flaccid paralysis, quadriparesis, and coma. The onset of symptoms is often delayed up to several weeks from administration.[131] Patients may progress to death even when therapy is discontinued. This neurotoxicity, however, is not common with the current recommended maximum dosage of 20 to 30 mg/m^2/day for 5 days. Mild neurologic symptoms are often reported, but severe neurotoxicity[128,129] and optic demyelination occur only occasionally.[132] Patients with signs or symptoms suggestive of significant neurotoxicity should receive a neurologic examination and, if warranted, therapy should be discontinued without rechallenging.

Nelarabine, another purine analog, has dose-limiting neurotoxicity, and 18% to 37% of patients in phase II trials develop grade 3 or 4

neurotoxicities.[133,134] The clinical presentation includes severe somnolence, convulsions, and peripheral neuropathy ranging from paresthesias to motor weakness. Several cases of ascending peripheral neuropathies and demyelination have been reported.[135] Therapy should be stopped if grade 2 toxicity is present because this may be irreversible.[136]

Fluorouracil can cause both acute and delayed neurotoxicity. Acute neurotoxicity manifests as cerebellar dysfunction or encephalopathy. Symptoms include gait ataxia, dysarthria, nystagmus, confusion, headache, disorientation, and lethargy. Seizures have been rarely reported. Delayed neurotoxicity presents as subacute multifocal leukoencephalopathy. Reports of cerebellar ataxia have also been reported with capecitabine, an oral prodrug of fluorouracil.[137–139] Polymorphisms in the *TYMS* and *DPYD* genes have been associated with the risk of fluoropyrimidine neurotoxicity due to increased exposure.[140,141] Uridine triacetate is an antidote that competes with toxic metabolites and reverses neurologic and other severe or life-threatening adverse effects from fluorouracil or capecitabine when administered promptly.[142]

Asparaginase and pegaspargase can cause encephalopathy, which presents most commonly as lethargy and confusion. Severe cerebral dysfunction occurs occasionally, and patients may present with stupor, coma, excessive somnolence, disorientation, hallucination, or severe depression. Symptoms can occur early (within days of administration of asparaginase) or late, depending on the treatment schedule. The suspected mechanism is the direct neurocytotoxic effect of aspartic acid, glutamic acid, and ammonia. The neurotoxicity is usually reversible, with the acute syndrome clearing rapidly and a delayed syndrome lasting several weeks.[128,143,144]

Multiple other anticancer agents may cause encephalopathy (**Table 94-5**). Recognition of neurotoxicity resulting from cytotoxic chemotherapy is often difficult because of comorbid conditions such as metastatic disease and other paraneoplastic syndromes, but it is important in assessing the need for potential dose modifications or even discontinuation of the agent. Several reviews provide detailed

explanations of signs and symptoms, mechanisms, and potential treatments for chemotherapy-induced neurotoxicities.[128,145]

Table 94-5
Neurotoxicity of Selected Chemotherapeutic Agents

Acute Encephalopathy	Chronic Encephalopathic Syndrome	Cerebellar Neuropathy	Peripheral Neuropathy	Cranial Neuropathy	Arachnoiditis (Intrathecal Therapy)	Autonomic Neuropathy	SIADH
Asparaginase	Cytarabine	Cytarabine	Bortezomib	Fluorouracil	Cytarabine	Vinblastine	Cyclophosphamide
Cisplatin	Methotrexate	Cisplatin	Brentuximab	Ifosfamide	Methotrexate	Vincristine	Vinblastine
Cytarabine	Nelarabine	Fludarabine	Cisplatin		Thiotepa	Vinorelbine	Vincristine
Fludarabine	Thiotepa	Fluorouracil	Docetaxel				Vinorelbine
Ifosfamide		Ifosfamide	Fluorouracil				
Methotrexate			Ifosfamide				
Nelarabine			Lenalidomide				
Procarbazine			Nelarabine				
			Paclitaxel				
			Thalidomide				
			Vinblastine

			Vinorelbine				

SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

Sources: Newton HB. Neurological complications of chemotherapy to the central nervous system. *Handb Clin Neurol*. 2012;105:903–916. doi:10.1016/B978-0-444-53502-3.00031-8; Magge RS, DeAngelis LM. The double-edged sword: neurotoxicity of chemotherapy. *Blood Rev.* 2015;29(2):93–100. doi:10.1016/j.blre.2014.09.012.

A.L.'s symptoms most likely are the result of CNS toxicity caused by both high-dose methotrexate and cytarabine. A decision regarding further treatment with these agents is complicated because omitting a dose or decreasing the dose of either of these agents could compromise the likelihood of a complete remission. High-dose cytarabine cerebellar toxicity may be irreversible. Therefore, the clinician may decide to discontinue cytarabine in A.L.'s future regimens. In addition, modifications of methotrexate, including dose reductions, may be necessary in future therapy for A.L.

CASE 94-7, QUESTION 2: What is the most likely medication causing A.L.'s numbness?

Peripheral neuropathy

Paresthesia (numbness and tingling) involving the feet and/or hands is an early subjective symptom of vincristine neurotoxicity, which often appears within the first days to weeks of therapy. Because A.L. received vincristine on days 1 and 8, it is reasonable to assume that her presentation of numbness in her extremities is secondary to the vincristine. This peripheral nerve toxicity is commonly bilateral and symmetric and is often referred to as a *stocking-glove neuropathy*. Symptoms initially consist of paresthesias, loss of Achilles reflex, and depression of deep tendon reflexes. Areflexia (absent reflexes) typically occurs in about 50% to 70% of patients treated with a cumulative dose >6 to 8 mg. In an effort to minimize these toxicities, capping each dose of vincristine at 2 mg has been a longstanding tradition. Although older patients appear to be more susceptible to paresthesias than are younger ones, almost all patients report some degree of paresthesias after combination chemotherapy that incorporates vincristine or vinblastine. Pain and temperature sensory loss are usually more pronounced than are vibration and proprioception sensory loss. Patients also may display motor weakness with a foot drop or muscle atrophy. Stumbling and falling that can occur with this peripheral neuropathy is not usually caused by muscle weakness; instead, it occurs in the dark when patients lose proprioception because they lack visual orientation. These complications are either partially or completely reversible, but recovery often takes several months.[146]

Other agents that share the peripheral nerve toxicity of vincristine include vinblastine, vinorelbine, cisplatin, etoposide, oxaliplatin, paclitaxel, docetaxel, cabazitaxel, ixabepilone, bortezomib, thalidomide, and lenalidomide, among others.[145] Unlike the vinca alkaloids (vincristine and vinblastine), most of these agents cause numbness only and not a loss of reflexes or weakness. However, patients may report sensory loss and pain. Antibody drug conjugates (ADCs) consist of potent cytotoxic drugs conjugated to antibodies via linkers, which allow for specific targeting of tumor cells while reducing systemic exposure to the cytotoxic drug. Multiple ADCs

(such as brentuximab vedotin, polatuzumab vedotin, trastuzumab emtansine, and enfortumab vedotin) include a potent microtubule inhibitor, similar to vincristine or vinblastine, as the cytotoxic drug. Neuropathy with these agents is again primarily sensory rather than motor, and is often dose limiting. With all agents, the incidence may be related to cumulative doses and individual risk factors such as a history of diabetic neuropathy.[147–149]

Many preventive strategies have been evaluated including amifostine, glutamine, glutathione, and vitamin E. However, evidence is limited by small sample sizes, and the studies lacked placebo-controlled randomized designs.[150] Treatment strategies are only palliative and include adjuvant pain medications such as tricyclic antidepressants, serotonin–norepinephrine reuptake inhibitors (SNRIs), anticonvulsants (pregabalin and gabapentin), and topical agents. Duloxetine, an SNRI, was studied in a phase III trial of patients with peripheral neuropathy due to prior treatment with single-agent taxane or platinum. Compared with placebo, duloxetine was associated with a larger average decrease in pain score. More patients receiving duloxetine experienced grade ≥2 fatigue.[151] Peripheral neuropathy is usually reversible, although resolution may take months. Several reviews provide detailed references for this information.[150,152,153] Avoidance of azole antifungals and other inhibitors of cytochrome P-450 (CYP) 3A4 is important in the prevention of neuropathy from vincristine as well as other microtubule inhibitors.[154]

Oxaliplatin causes peripheral neuropathies that differ from other anticancer agents. Oxaliplatin-induced neurotoxicity manifests as an acute neurosensory complex as well as a cumulative sensory neuropathy. Hyperexcitability of peripheral nerves causes an 85% to 95% incidence of paresthesias and dysesthesias of the hands, feet, and the perioral region. Laryngeal dysesthesias have been described as well. These effects are precipitated by exposure to cold. This cold neuropathy is reversible and generally resolves in between doses. Oxaliplatin also causes a cumulative dose-limiting chronic neuropathy that is reversible several months after completion of therapy. Dose modifications for patients with persistent

neurotoxicities typically involve delaying therapy until clinical improvement.

Case 94-7, Question 3: What is the significance of A.L.'s lid lag?

Cranial nerve toxicity

Cranial nerve toxicity occurs in 1% to 10% of patients receiving vinca alkaloids, and most patients present with ptosis or ophthalmoplegia,[155,156] probably related to damage to the third cranial nerve. Toxicity to other cranial nerves can cause trigeminal neuralgia, facial palsy, depressed corneal reflexes, and vocal cord paralysis—and may occur in the first few days to weeks after administration.[157] Other nerve toxicities associated with the vinca alkaloids include jaw pain, which can occur as early as after the first or second dose[158]; the pain usually resolves spontaneously and does not recur with subsequent doses. A.L.'s eyelid lag probably is caused by vincristine. Ifosfamide, vinblastine, carboplatin, and cisplatin have also been reported to cause cranial neuropathies.

Ototoxicity

Ototoxicity, characterized by a progressive, high-frequency, sensorineural hearing loss, commonly occurs with cisplatin,[159,160] most likely as a result of a direct toxic effect on the cochlea. Ototoxicity occurs more frequently at higher dosages, worsens with concurrent cranial radiation therapy, and appears to be more pronounced in children. Other risk factors include regular use of nonsteroidal anti-inflammatory drugs, a history of noise exposure, and renal insufficiency before cisplatin.[161,162] The reversibility of cisplatin ototoxicity is questionable. At some centers, routine audiometric tests are performed in patients receiving cisplatin. Early cessation of cisplatin may result in greater hearing improvement. Ototoxicity has also been reported in patients receiving carboplatin.[160] If ototoxicity is suspected, a hearing test should be

performed and therapy discontinued if alternate treatments are available.

Autonomic neuropathy

Case 94-7, Question 4: What is the cause of A.L.'s constipation, and how might this problem have been prevented?

Vincristine, as well as vinblastine, commonly causes autonomic neuropathy. The earliest symptoms (colicky abdominal pain with or without constipation) are reported by one-third to one-half of patients receiving these agents.[145,155] Because severe constipation can progress to or include adynamic ileus, prophylactic laxatives are recommended on a regular basis for patients receiving vincristine and vinblastine. Stimulant laxatives such as the senna derivatives or bisacodyl are believed to be the most effective agents, and stool softeners also may be used concurrently. No compelling evidence suggests, however, that laxatives prevent constipation. Other less frequent manifestations of autonomic dysfunction associated with vinca alkaloids include bladder atony with urinary retention, impotence, and orthostatic hypotension.[163,164] Patients should be monitored carefully for these signs or symptoms and receive appropriate management after diagnosis.

A.L. is experiencing multiple signs and symptoms of neurotoxicity including CNS toxicity from methotrexate and cytarabine as well as peripheral neuropathy, autonomic neuropathy in the form of constipation, and cranial nerve toxicity from vincristine. Management overall is supportive and may be reversible after therapy cessation. Early recognition and intervention are pivotal to the management of various neurotoxicities. A.L.'s constipation could not have been prevented but can be managed with stool softeners and stimulant laxatives.

CARDIOTOXICITY

Cardiomyopathy

Doxorubicin

CASE 94-8

QUESTION 1: D.A., a 35-year-old male with stage IV Hodgkin lymphoma, received ABVD (doxorubicin 25 mg/m^2 IV days 1 and 15, bleomycin 10 units/m^2 IV on days 1 and 15, vinblastine 6 mg/m^2 IV on days 1 and 15, and dacarbazine 375 mg/m^2 IV on days 1 and 15) for six cycles and concurrent radiation therapy to a large mediastinal mass. Ten years after completion of treatment he presents to clinic and is found to have tachycardia, shortness of breath (SOB), and a nonproductive cough. Physical examination reveals neck vein distension, pulmonary rales, and ankle edema. Past medical history is significant for controlled hypertension.

What is the most likely cause of D.A.'s current symptoms?

D.A. is experiencing symptoms of congestive heart failure (CHF) most likely caused by doxorubicin therapy. Doxorubicin, an anthracycline, can cause a dose-dependent cardiomyopathy that generally occurs with repeated administration. Anthracyclines are believed to cause toxicity to cardiomyocytes mainly via inhibition of topoisomerase 2β.[165] Doxorubicin causes myocyte damage by a mechanism that differs from its cytotoxic effect on tumor cells. Because myocytes stop dividing in infancy, they presumably would not be affected by an agent whose cytotoxicity relies on actively cycling cells. Other mechanisms have been proposed to explain the cardiac toxicity associated with anthracyclines including the formation of reactive oxygen species.[166,167] The association of anthracycline-induced cardiotoxicity with other agents administered concomitantly, monitoring techniques, and therapies to prevent and treat this condition have been reviewed.[166,168–170]

D.A.'s presentation is fairly typical of doxorubicin-induced cardiomyopathy, although he has no significant risk factors usually associated with CHF. The total cumulative dose of doxorubicin is the most clearly established risk factor for CHF.[171] Patients, such as D.A., who are receiving bolus doses of doxorubicin at the standard 3-week interval face little risk of CHF until a total dose of 450 to 550 mg/m^2 has been reached.

Older data indicated a relatively low incidence of cardiac dysfunction in patients with a cumulative doxorubicin dose <400 mg/m^2.[171] More recent findings support cardiac dysfunction at lower cumulative doses than were previously described. A pooled analysis of phase III trial data in patients treated with doxorubicin demonstrated a cumulative incidence of cardiac events (defined as a decrease in left ventricular ejection fraction [LVEF] or occurrence of CHF) in 9% of patients at a cumulative dose of 250 mg/m^2, 18% at 350 mg/m^2, and 38% at 450 mg/m^2.[172] The Childhood Cancer Survivor Study evaluated 14,358 five-year survivors of cancer who were diagnosed at the age of 21 or younger between 1970 and 1986. They were compared to 3899 siblings of cancer survivors.[173] Exposure to 250 mg/m^2 or more of anthracyclines increased the relative hazard of CHF, pericardial disease, and valvular abnormalities by two to five times compared with survivors who had not been exposed to anthracyclines. Cardiac radiation exposure of 15 Gy or more also increased the relative hazard of CHF, myocardial infarction, pericardial disease, and valvular abnormalities by two to six times compared to nonirradiated survivors. The cumulative incidence of adverse cardiac outcomes in cancer survivors continued to increase up to 30 years after diagnosis. A threshold of 250 mg/m^2 of doxorubicin is reflected in a guideline of the American Society of Clinical Oncology (ASCO).[170]

Other factors that could increase D.A.'s risk of experiencing doxorubicin cardiomyopathy include mediastinal radiation therapy, preexisting cardiac disease, and hypertension. Young children, as well as older patients, are likely to experience CHF at a lower cumulative dose. Concurrent chemotherapy agents (eg, cyclophosphamide, etoposide, mitomycin, melphalan, trastuzumab, paclitaxel, vincristine, and bleomycin) may also potentiate doxorubicin cardiac toxicity.[166,168] When patients receive paclitaxel and doxorubicin, the risk of cardiac toxicity appears to be related to the sequence and proximity of the infusions. In a pharmacokinetic study, paclitaxel increased the area under the curve (AUC) of doxorubicin and its active metabolite, doxorubicinol, when paclitaxel administration immediately preceded doxorubicin. Therefore,

doxorubicin should be given at least 30 minutes before paclitaxel. The relationship between risk factors and the total cumulative dose of doxorubicin is sufficiently strong to warrant guidelines restricting the total cumulative dose of doxorubicin to 450 mg/m^2 in patients with one or more identified risk factors including mediastinal radiation, elderly age, and preexisting cardiovascular disease (high-risk patients) and to 550 mg/m^2 in patients without any of these aforementioned risk factors (low-risk patients).

It is unusual that D.A., a 35-year-old male who has received a cumulative dose of only 200 mg/m^2 of doxorubicin, would be presenting with symptoms of CHF. Mediastinal radiation therapy or an undiagnosed cardiac disease may, however, have contributed to this event. In addition, Hodgkin lymphoma involving the myocardium may be responsible for this presentation.

Cardiac Monitoring

Case 94-8, Question 2: Should D.A. have received routine cardiac monitoring while he was receiving doxorubicin?

Doxorubicin

Prevention of cardiomyopathy is achieved primarily by limiting the total cumulative dose. However, this strategy cannot entirely prevent cardiomyopathy because individual tolerance to doxorubicin varies such that cardiotoxicity may occur before the arbitrary dose threshold, and some clinical situations warrant exceeding the dose threshold to achieve positive chemotherapeutic treatment outcomes.

Early efforts to prevent cardiomyopathy focused on monitoring systolic time intervals, QRS voltage loss, or ST-T segment changes on an electrocardiogram. These changes were too nonspecific or occurred too late to be useful; however, serial echocardiography (ECHO) has been useful. Current monitoring for anthracycline cardiomyopathy includes assessment of the patient's LVEF, which is a measure of the heart's systolic function using ECHO, radionuclide

cardiac angiography (multiple gated acquisition [MUGA]), or endomyocardial biopsy. The use of MUGA for early detection of doxorubicin-induced cardiac dysfunction has been investigated extensively.[174] A MUGA can accurately detect functional cardiac status, but it is not particularly sensitive in detecting patients who have early myocyte damage. Augmenting the MUGA with exercise appears to give a more accurate picture of functional cardiac reserve. Because myocyte damage usually occurs days to weeks after treatment with doxorubicin, the MUGA should be obtained just before, rather than just after, a course of the agent. Although guidelines vary, most suggest regular cardiac function assessment by evaluation of LVEF by either ECHO or MUGA at defined intervals.[165,168,170]

D.A. should have received a baseline assessment of his LVEF either by ECHO or MUGA before his first cycle of ABVD. During courses of therapy, ongoing LVEF monitoring for D.A. would not have been routinely recommended unless he was approaching his lifetime cumulative dose or there were clinical signs or symptoms of CHF.

Additional assessments should be obtained if a patient shows signs or symptoms of CHF, and may be obtained periodically in low-risk asymptomatic patients and high-risk patients based on the presence of risk factors and provider judgment. The decision to discontinue anthracycline therapy because of cardiotoxicity is complex and must be considered in the context of treatment intent and the patient's comorbid conditions. Collaboration with a cardiologist is recommended for patients with concern for or evidence of treatment-induced cardiotoxicity.[170]

Other Anthracyclines

Daunorubicin differs structurally from doxorubicin only by hydroxylation of the 14th carbon. Cardiac toxicities are similar for both drugs, although somewhat higher cumulative doses of daunorubicin are typically tolerated.[175] Although idarubicin appears less cardiotoxic than does doxorubicin in animal models and

daunorubicin in some early clinical trials, other studies show equivalent myelosuppressive doses can cause cardiotoxicity comparable to that of doxorubicin and daunorubicin.[176–178] Epirubicin also has an incidence of demonstrated CHF.[179] For all anthracyclines, risk factors for CHF appear to be the same, and similar assessments should be undertaken to monitor for cardiotoxicity. Mitoxantrone is an anthracenedione that is structurally similar to the anthracyclines. Guidelines for monitoring doxorubicin-induced cardiotoxicity should also be followed with mitoxantrone therapy to minimize the risk of CHF.[168]

Prevention

Case 94-8, Question 3: Could D.A.'s CHF have been prevented by the use of a different dose or dosing schedule or by an agent that protects the myocardium?

Altering the dose schedule of doxorubicin to more frequent, smaller doses while maintaining dose intensity has consistently resulted in reduction of cardiotoxicity without obvious compromise of antitumor effects.[180–184] Several reports suggest that peak plasma levels, as well as cumulative dose, have an important relationship to doxorubicin cardiotoxicity. Low doses of doxorubicin administered weekly or prolonged continuous IV infusions (48–96 hours) can be relatively cardiac sparing, allowing higher cumulative doses to be administered. In a retrospective, uncontrolled study of 1000 patients receiving weekly doxorubicin, a total dose of 900 to 1200 mg/m^2 of doxorubicin given in weekly fractions had the equivalent cardiotoxicity of 550 mg/m^2 given in every-3-week fractions.[181] In patients with preexisting CHF or those who have exhibited CHF, a continuous-infusion schedule of anthracyclines rather than bolus doses may be considered. The concurrent use of drugs that might minimize the risk of cardiotoxicity without compromising efficacy can be considered as well.

Preventive strategies include management of modifiable cardiovascular risk factors, radiation methods that limit exposure to the heart, administration via continuous infusion instead of slow IV push, the use of liposomal doxorubicin, and administration of dexrazoxane.[170] Dexrazoxane is a chemoprotectant that reduces the incidence and severity of cardiomyopathy. It has been FDA approved for patients with metastatic breast cancer but is often considered for any patient who has received a cumulative doxorubicin dose of 300 mg/m^2 and will continue to receive doxorubicin therapy. The recommended dosing ratio of dexrazoxane to doxorubicin is 10:1 slow IV push 30 minutes before starting doxorubicin. Currently, the ASCO guidelines do not support the routine use of dexrazoxane unless a patient is planned to receive doxorubicin doses >250 mg/m^2.[170]

A Cochrane review was conducted of 10 RCTs involving 1619 adult and pediatric patients with cancer who received an anthracycline with or without dexrazoxane.[185] The majority of patients were adults with advanced breast cancer with no prior anthracycline therapy or cardiac dysfunction receiving doxorubicin or epirubicin. Dexrazoxane was administered with initial anthracycline treatment in all or the majority of patients in 8 of the 10 trials. Dexrazoxane dosing varied from 6.25:1, 10:0, to 20:1. The meta-analysis showed a benefit in favor of dexrazoxane, with reduced incidence of both clinical and subclinical heart failure. There were no significant differences between the treatment groups with regard to response rate, progression-free survival, or overall survival.

A review and meta-analysis of 55 RCTs in patients receiving anthracyclines showed that the risk of cardiotoxicity was significantly decreased with liposomal doxorubicin versus conventional doxorubicin (odds ratio, 0.18; 95% confidence interval, 0.08–0.38).[186] The majority of patients were females with advanced breast cancer. Despite reduced cardiotoxicity, liposomal doxorubicin has not replaced standard doxorubicin in current treatment regimens secondary to high cost and lack of evidence showing equivalency. An established equivalent dose of liposomal preparations to

conventional doxorubicin has not been confirmed, and the dose varies depending on the disease state and regimen.

D.A.'s CHF may have been prevented with continuous-infusion doxorubicin or the use of dexrazoxane; however, because he had not approached a cumulative dose that warranted alternative strategies, this would not have been part of the standard management plan for a patient receiving their first of several cycles of ABVD.

Management

CASE 94-8, QUESTION 4: How should D.A.'s doxorubicin-induced CHF be managed clinically?

Anthracycline-induced CHF presents similarly to other forms of biventricular CHF and may occur within 1 year of treatment, or many years later.[187] Treatment of anthracycline-induced CHF should follow an approach similar to cardiomyopathy induced by other means. Often, these measures are ineffective. The clinical course is variable, with some patients showing stable disease and others showing improvement. Before cardiotoxicity was a widely recognized toxicity, the course of anthracycline-induced CHF was characterized by a rapid progression that generally led to death within weeks. Clinical outcomes are better now, likely because of faster recognition, anthracycline discontinuation after initial symptoms, and improved treatment options for CHF (including spironolactone, β-blockers, angiotensin-converting enzyme [ACE] inhibitors, angiotensin II receptor blockers, and diuretics), which have decreased morbidity and mortality in non–anthracycline-induced CHF. Enalapril was evaluated to determine whether it would prevent cardiac function decline in a randomized, double-blind, placebo-controlled study of pediatric patients with cancer who were at least 2 years out from treatment with anthracyclines and had evidence of CHF. Patients received enalapril at 0.05 mg/kg/day, and this dose was progressively escalated to 0.10 mg/kg/day, and finally 0.15

mg/kg/day if there were no adverse effects. Although enalapril did not increase exercise intolerance, it did increase left ventricular end-systolic wall stress in the first year of treatment. Side effects included dizziness, hypotension, and fatigue.[188,189] An additional trial evaluated 201 patients with anthracycline-induced cardiomyopathy. Enalapril and carvedilol were initiated as tolerated as soon as LVEF impairment was observed. Complete resolution of CHF was observed in 85 (42%) patients, and an additional 26 (13%) demonstrated a partial response. Patients who had heart failure therapy initiated closer to the time of observation of their LVEF impairment had a better response. No responses were observed in patients who had heart failure therapy initiated >6 months from the end of their anthracycline regimen.[190] D.A.'s cardiomyopathy should be managed conservatively with an ACE inhibitor such as enalapril and fluid restriction with the addition of diuretics as necessary.[191]

Human Epidermal Growth Factor Receptor 2–Targeted Therapies

Cardiac dysfunction is the principal adverse effect of trastuzumab. When used alone, signs and symptoms of CHF (eg, dyspnea, increased cough, peripheral edema, S_3 gallop, and reduced ejection fraction) have been reported in 3% to 7% of patients receiving trastuzumab therapy. Of these patients, 5% had New York Heart Association (NYHA) class III or IV heart failure. The use of trastuzumab in combination with chemotherapy (including an anthracycline) in patients (*N* = 469) with metastatic breast cancer was associated with a 27% incidence of cardiotoxicity compared with 8% incidence in the anthracycline-alone arm. In these same patients, the incidence of NYHA class III or IV heart failure was 16% in the trastuzumab and chemotherapy arm versus 3% in patients receiving anthracyclines alone. In addition, heart failure occurred in the combination paclitaxel and trastuzumab arm, with an overall incidence of 13% and 2% (classes III and IV, respectively) versus a 1% incidence in the paclitaxel-alone arm.[192] A meta-analysis of five

randomized trials of adjuvant trastuzumab also showed a 2.5-fold higher risk of cardiotoxicity following trastuzumab administration.[193]

Although the exact mechanism behind trastuzumab-induced cardiotoxicity is not fully known, it is thought that the neuregulin (NRG)–ERBB pathway plays a key role. HER2 is one of the tyrosine kinases of the EGFR or ERBB family, and NRG–ERBB signaling is involved in cardiac development and physiology.[194] The toxicity seems to be direct and not dependent on cumulative dose or treatment duration. Trastuzumab-associated cardiac toxicity usually responds to standard medical treatment or discontinuation of the drug.[166] Before, and periodically during, treatment with trastuzumab, patients should undergo cardiac evaluation to assess LVEF. Therapy should be discontinued if patients exhibit a clinically significant decrease in left ventricular function.

The other HER2 targeting agents (lapatinib, pertuzumab, ado-trastuzumab emtansine, neratinib, tucatinib, and trastuzumab deruxtecan) may have a more favorable cardiac safety profile than does trastuzumab. A decline in cardiac function has also been reported in a pooled analysis of 3689 patients with breast cancer receiving lapatinib. The incidence was 1.6% (60 patients). Twelve of the patients had prior anthracyclines and 14 had received prior trastuzumab.[195] Routine cardiac evaluation for patients on pertuzumab, ado-trastuzumab emtansine, and trastuzumab deruxtecan is recommended. No routine cardiac monitoring is recommended for lapatinib, tucatinib, or neratinib at this time.

Tyrosine Kinase Inhibitors

The multitargeted TKIs exhibit a range of cardiovascular toxicities. Because these agents are dosed chronically, toxicities may develop relatively late in the course of therapy. Imatinib has been associated with the development of CHF. A single-institution series reviewed all patients (*N* = 1276) who had received imatinib within their institution. Twenty-two patients (1.2%) exhibited CHF. Eleven patients continued imatinib with the addition of diuretics, β-blockers, and ACE inhibitors. Five of those who continued therapy with imatinib had

dose reductions. The remaining 11 discontinued imatinib (3 secondary to disease progression, 6 secondary to CHF, and 2 were deaths).[196] Patients receiving imatinib should be monitored for symptoms and signs of heart failure.[197] Dasatinib has also been associated with heart failure and ventricular dysfunction.[198] Ponatinib may cause heart failure (in up to 9% of patients), myocardial infarction, and arrhythmias.[199] Sorafenib and sunitinib have been associated with a decline in cardiac ejection fraction in 5% and 14% of 86 patients, respectively, treated for metastatic renal cell cancer.[200] Other TKIs associated with CHF include pazopanib and vemurafenib.[168] Patients experiencing cardiomyopathy on targeted agents are treated similarly to those patients with anthracycline-induced cardiomyopathy. Discontinuation of the offending agent or reduction of dose with concurrent pharmacologic management of CHF is warranted. Two reviews of proposed mechanisms and reported incidence of targeted therapy–induced cardiomyopathy therapies provide a summary of current evidence.[166,201]

Arrhythmias

Electrocardiographic (ECG) changes have been observed during or after treatment with doxorubicin, other anthracyclines, cisplatin, etoposide, paclitaxel, cyclophosphamide, mechlorethamine, and arsenic trioxide. ST–T segment changes, decreases in voltage, T-wave flattening, and atrial and ventricular ectopy are most common. Arrhythmias may occur in 6% to 40% of patients receiving bolus doxorubicin.[202] Paclitaxel also caused significant arrhythmias and conduction defects in phase I and II trials[203]; most patients experienced sinus bradycardia. Doxorubicin and paclitaxel are used in many outpatient regimens, so this toxicity is seen frequently. Arsenic trioxide, used in the treatment of APL, can cause QT interval prolongation and complete atrioventricular block. Dasatinib, nilotinib, lapatinib, pazopanib, and sunitinib have also demonstrated QT prolongation.[168] The underlying mechanisms for these prolongations are not yet understood. Nilotinib, with a reported incidence of 1% to 10%, carries a boxed warning regarding prolongation of the QT

interval. Nilotinib carries specific recommendations for monitoring of ECGs; baseline, 7 days after initiation, after any change of dose, and routinely thereafter.[204] However, there are no specific recommendations for many other TKIs.

QT prolongation can lead to a torsades de pointes–type ventricular arrhythmia. Before initiating therapy, an ECG should be performed, and serum electrolytes, including potassium and magnesium, should be assessed and corrected. In addition, all concomitant medications, both anticancer and other supportive care medications that are known to prolong the QT interval, should be assessed for potential discontinuation to reduce risk.[168]

Ibrutinib demonstrates an increased rate of developing atrial fibrillation of 4% to 10% over what is expected in the general population.[205] This may be due to off-target binding sites and indirect effects on other signaling pathways. BTK inhibitors with less off-target effects, acalabrutinib and zanubrutinib, seem to have a lower risk of atrial fibrillation. A phase III RCT comparing zanubrutinib and ibrutinib showed significantly lower rates of atrial fibrillation with zanubrutinib (2% vs 15% with ibrutinib).[206] In most instances, therapy with a BTK inhibitor can be safely continued because many patients will not have recurrence of the abnormal heart rhythm.

Many other anticancer agents not mentioned previously occasionally cause a rhythm disturbance, but these are limited to a few scattered reports and should not be considered clinically significant. Therapy should not be discontinued unless the patient experiences a serious cardiac arrhythmia.

Hypertension

An increased incidence of hypertension has been observed in patients receiving VEGF-targeted therapy including bevacizumab, sunitinib, sorafenib, axitinib, regorafenib, and pazopanib, among others. Bevacizumab-related hypertension may be dose related; it can occur at any time during therapy and is reported to have a 22% to 32% incidence. Hypertension is usually ≤grade 3 and can be controlled with antihypertensive medications.[207] An increased risk of

myocardial ischemia and infarction has been observed with the use of sorafenib in patients with metastatic renal cell cancer in a phase III study.[189] Patients receiving these agents should be routinely monitored for hypertension, and antihypertensives (generally ACE inhibitors or calcium channel blockers) promptly initiated. In patients with uncontrolled hypertension, anticancer therapy medication may need to be dose reduced or discontinued. Several consensus statements and guidelines have been published to assist in the hypertension management of patients on VEGF inhibitors.[208,209]

Angina and myocardial infarction

Fluorouracil and capecitabine have been associated with angina pectoris and myocardial infarction. In a systematic review including 30 studies, symptomatic cardiotoxicity occurred in 0% to 20% of the patients treated with fluorouracil and in 3% to 35% with capecitabine. The most common symptom was chest pain (0%–19%) followed by palpitations (0%–23%), dyspnea (0%–8%), and hypotension (0%–6%). It appears to occur more frequently in patients receiving multiple-day continuous infusions.[210] Direct myocyte damage is observed from animal studies; however, human studies suggest that coronary artery spasm is the most likely cause of angina. Because the chest pain associated with fluorouracil responds to nitrates, this problem, theoretically, could be managed prophylactically or therapeutically with long-acting nitrates or calcium channel blockers.[211] Other agents have been associated with myocardial ischemia (including, but not limited to, temsirolimus, docetaxel, paclitaxel, imatinib, and ponatinib) based on case reports in the literature.[168,212,213]

NEPHROTOXICITY

Cisplatin

CASE 94-9

QUESTION 1: T.J., a 58-year-old male with nonresectable head and neck cancer, is being treated with cisplatin 100 mg/m^2 IV on day 1 and fluorouracil 1 g/m^2/day IV continuous infusion on days 1 to 4. He received 1 L of normal saline (NS) before and 1 L of NS after his cisplatin on day 1. He presents today for the third cycle of this regimen. T.J.'s labs reveal an estimated creatinine clearance (CrCl) of 75 mL/minute, decreased from 110 mL/minute at baseline. Other abnormalities include serum magnesium of 1.2 mEq/dL; all other electrolyte values are within the normal range.

Is cisplatin responsible for T.J.'s decreased glomerular filtration rate (GFR) and serum magnesium levels?

Cisplatin, a platinum heavy metal complex, is active against many solid tumors and remains as part of first-line therapy for lung, head and neck, and testicular cancers. The major dose-limiting toxicity of cisplatin is nephrotoxicity, and various renal and electrolyte disorders, both acute and chronic, have been associated with cisplatin. Before the need for vigorous hydration was recognized, cisplatin often caused acute renal failure. With the use of vigorous hydration, acute renal failure is uncommon; however, tubular dysfunction and decreased GFR remain problematic.

Acute kidney injury from cisplatin is associated with older age, higher dose, history of hypertension, and hypoalbuminemia.[214] Morphologic damage is greatest in the straight segment of the proximal renal tubules, where the highest concentration of platinum occurs. Acute and cumulative renal tubular damage has been demonstrated by increased urinary excretion of proximal tubular enzymes, such as β_2-microglobulin, alanine aminopeptidase, and *N*-acetyl glucosamine. More recently, the renal uptake carrier organic cation transporter 2 (OCT2) and organic anion transporters 1 and 3 (OAT1 and OAT3) have been implicated.[215] Acute renal failure occurs from acute proximal tubular damage and presents as polyuria in the first 24 to 48 hours when urine osmolality declines, but GFR is normal. Polyuria will decline, and then 72 to 96 hours later, polyuria increases again, urine osmolality declines, and the GFR declines as well and is persistent. Increases in proximal tubular enzymes correlate well with urinary excretion of protein and magnesium as

well as decreased reabsorption of salt and water in the proximal tubules. T.J. has hypomagnesemia, which is the most common electrolyte abnormality caused by cisplatin. Hypomagnesemia appears to be dose related and may occur after a single treatment. Despite replacement with oral magnesium, renal losses of magnesium and decreased serum magnesium levels can persist for months or even years after completion of cisplatin therapy. Hypocalcemia, hyponatremia, and hypokalemia occur less frequently. The cause of these electrolyte abnormalities is thought to be similar to that of hypomagnesemia as a proximal tubular defect that interferes with the reabsorption of these electrolytes.[216,217]

Chronic renal toxicity associated with cisplatin presents as a decrease in the GFR. Published reports suggest that the GFR decreases by 12% to 25% in most patients receiving multiple courses.[217] The decrease appears to be persistent and only partially reversible. An increase in serum creatinine (SCr) or a decrease in CrCl does not necessarily reflect the decline in GFR. A long-term follow-up study of 821 adults exposed to cisplatin with a median follow-up of 6 years found that acute kidney injury had occurred in 31.5% of patients, but <3% had an estimated glomerular filtration rate (eGFR) <29 mL/minute/1.73 m^2 at any time after the first cycle of cisplatin, and none were known to require dialysis.[218]

T.J. is at risk for chronic renal toxicity because he has previously received two other cycles. Renal function of patients receiving cisplatin therapy should be evaluated, because dose reductions of cisplatin may be necessary if the CrCl decreases. T.J.'s decreased GFR and low serum magnesium likely are caused by repeated cycles of cisplatin therapy. Although a dose reduction of cisplatin generally is not recommended for CrCls that are >60 mL/minute, the clinician should provide T.J. with adequate and aggressive hydration to prevent cisplatin nephrotoxicity. Despite preventive methods, many patients will still experience declines in GFR as seen in T.J. In addition, T.J. should receive an oral magnesium supplement. When large doses of magnesium are necessary, diarrhea often limits the use of oral supplementation. IV administration should be used if higher magnesium doses are required. Patients should undergo

frequent measurements of their electrolytes, including magnesium, to minimize potential complications.

Prevention

Case 94-9, Question 2: What measures should be taken to prevent further cisplatin nephrotoxicity in T.J.?

Measures used to minimize or prevent cisplatin-induced nephrotoxicity include hydration with saline and prophylactic magnesium. Incorporation of hydration with saline and magnesium is the standard of care for all patients receiving cisplatin. Patients should be vigorously hydrated before and after cisplatin administration.[216,217,219] A loop diuretic (eg, furosemide) may be required in elderly patients to eliminate excess sodium or in patients with compromised cardiac reserve, but these diuretics should not be used routinely to prevent nephrotoxicity. In addition, mannitol (25–50 g) has been administered just before chemotherapy to prevent cisplatin-induced renal artery vasoconstriction, which can increase the concentration of platinum in the renal tubules, although this is controversial and not supported by current evidence.[220] Many patients may also benefit from prophylactic magnesium supplementation. Patients who received prophylactic magnesium during and 16 mEq IV daily during a 5-day course of cisplatin followed by 60 mEq orally (20 mEq three times daily) between doses of cisplatin experienced less nephrotoxicity compared with those who received no supplements in a prospective trial of 16 patients with testicular carcinoma.[221] Patients should undergo frequent measurements of electrolytes, including magnesium, to minimize potential complications.

T.J. should be encouraged to increase his oral hydration to 2 to 3 L/day for several days after this cycle of chemotherapy. In addition, he should take oral magnesium supplementation between courses. For cycle 4 of his chemotherapy, he should receive 3 to 4 L of saline the day of cisplatin administration.

Patients who experience renal dysfunction commonly have the dose of cisplatin reduced. Guidelines to modify the dosage of cisplatin in patients with decreased renal function are available. Most suggest a 50% dosage reduction when the GFR decreases to 30 to 60 mL/minute and discontinuation when the GFR falls to <10 to 30 mL/minute. Percentage dose reductions are relative to the recommended dose for a specific cancer in a given combination chemotherapy regimen.[222] Because the cisplatin dose ranges from 50 to 120 mg/m^2, the precise dose for a patient with a GFR of <60 mL/minute must be individualized. T.J. should have another SCr drawn to estimate CrCl before his next cycle. As long as his CrCl is maintained above 60 mL/minute, then no dose reductions of his cisplatin are necessary. If a tumor type is known to be responsive to carboplatin and efficacy will not likely be compromised, substitution of carboplatin should be considered because it does not cause nephrotoxicity. Carboplatin is excreted primarily by the kidneys, and the dose is calculated by the Calvert equation,[223] which accounts for decreased GFR (discussed further in Chapter 98, Lung Cancer). Therefore, patients who have decreased renal function receive lower doses than do those with normal function. Other agents requiring dose adjustments or omission for renal dysfunction are shared in **Table 94-6**.

Table 94-6

Select Anticancer Agents Requiring Dosage Modifications or Dosage Omissions in Renal Insufficiency

Bleomycin	Lenalidomide
Capecitabine	Lomustine
Carboplatin	Melphalan
Carmustine	Methotrexate
Cisplatin	Mitomycin
Cytarabine	Pemetrexed
Dacarbazine	Pentostatin
Fludarabine	Topotecan

Ifosfamide

Other nephrotoxic agents

Proximal Renal Tubular Dysfunction

Other agents reported to cause renal tubular defects include cyclophosphamide, ifosfamide, lomustine, carmustine, pemetrexed, and azacitidine.[216,219] Nephrotoxicity appears to be related to the total cumulative dose for carmustine and lomustine, but not necessarily for ifosfamide. Renal abnormalities associated with high doses of bolus ifosfamide have led to the use of fractionated doses and a reduced incidence of toxicity.[216] Most patients show signs and symptoms consistent with proximal tubular dysfunction.

Renal toxicity of the proximal renal tubule may result in several electrolyte imbalances, such as loss of protein, glucose, bicarbonate, phosphorous, and potassium. Proteinuria and glycosuria may also occur. SCr, bicarbonate, potassium, urinary pH, protein, and glucose should be monitored closely in patients receiving these agents. Because the reversibility of the lesions is reported to be highly variable and a significant number of patients who exhibit severe renal toxicity with these agents require dialysis,[216] patients should discontinue treatment with these agents if there is evidence of significant and persistent changes in SCr or electrolytes.

Proteinuria

Bevacizumab, an anti-VEGF monoclonal antibody, is associated with proteinuria and the reported incidence ranges from 21% to 46% of patients.[224] Although bevacizumab is the anti-VEGF agent most

noted with this toxicity, ramucirumab (another anti-VEGF monoclonal antibody) and oral TKIs that affect the VEGF receptor such as axitinib have also been associated with proteinuria.[225,226] Mechanisms for this toxicity include microcirculatory angiogenesis and inhibition of nitric oxide synthesis, leading to an increase in peripheral resistance and endothelial dysfunction. Glomerular injury from VEGF inhibition may also lead to renal thrombotic microangiopathy and glomerulonephritis. Severe nephrotic syndrome has been observed in 1% to 2% of patients.[211,224,227] Patients receiving bevacizumab and ramucirumab should be monitored routinely for proteinuria by dipstick urinalysis. The manufacturer recommends that patients with a ≥2+ urine dipstick reading undergo further assessment with a 24-hour urine collection. In addition, it is recommended to delay further administration of bevacizumab when >2 g of proteinuria in 24 hours is observed. Therapy may be reinitiated at a reduced dose when the proteinuria observed is <2 g in 24 hours. Proteinuria is most often mild in patients and is usually reversible upon discontinuation of the agent. The highest incidence of severe proteinuria requiring permanent discontinuation has been seen in patients with metastatic renal cell carcinoma.[228]

CASE 94-10

Question 1: J.R., a 15-year-old boy with osteogenic sarcoma of the right knee, is to be treated with chemotherapy consisting of high-dose methotrexate with leucovorin rescue, doxorubicin, and cisplatin. The dose of methotrexate is 12 g/m^2 IV administered over 4 hours.

What precautions are necessary to prevent renal and other toxicities associated with high-dose methotrexate therapy in J.R.?

Methotrexate normally is not nephrotoxic, although 90% of the agent is excreted unchanged in the urine; however, acute tubular obstruction can occur with high-dose methotrexate if appropriate precautions are not taken. Acute tubular obstruction is caused by tubular precipitation of methotrexate, which is poorly soluble at a pH <7.0. To prevent this, J.R. should receive alkaline hydration and brisk

diuresis to produce a urine pH >7.0 and adequate urine output. A urine pH >7.0 usually can be ensured by administration of 50 to 150 mEq/L sodium bicarbonate within the hydration fluid. J.R.'s urine output and pH must be monitored closely to prevent acute tubular obstruction during this period. The only preventive strategy for acute tubular obstruction associated with high-dose methotrexate therapy is appropriate attention to optimal urinary output before, and for at least 24 hours after, high-dose methotrexate administration and urinary alkalization.[229]

If J.R. has existing renal insufficiency, methotrexate excretion will be decreased, leading to higher systemic exposure. As a result, myelosuppression and mucositis can become more problematic. Leucovorin (folinic acid) is a reduced form of folic acid given after methotrexate administration to selectively rescue normal cells from these adverse effects. Because leucovorin is already in reduced form, it can bypass the action of dihydrofolate reductase and not interfere with methotrexate's inhibition of this enzyme. Leucovorin rescue should be initiated 24 hours after the high-dose methotrexate infusion. Methotrexate levels are necessary to guide leucovorin dosing. Leucovorin rescue does not affect the renal clearance of methotrexate and will not prevent renal injury. A rescue agent, glucarpidase, is indicated for the treatment of toxic methotrexate concentrations in patients with delayed methotrexate clearance due to impaired renal function. Glucarpidase is a recombinant bacterial carboxypeptidase enzyme that converts methotrexate to its inactive metabolites and provides an alternative route for methotrexate elimination in patients with renal dysfunction and signs or symptoms of methotrexate toxicity.[230]

HEMORRHAGIC CYSTITIS

Case 94-10, Question 2: After J.R.'s surgery, it is decided to add ifosfamide to his treatment. What bladder toxicity occurs with ifosfamide that requires attention before its administration?

Pathogenesis

Ifosfamide is a structural analog of cyclophosphamide belonging to the oxazaphosphorine class of antitumor alkylating agents, which must be hydroxylated and activated by the CYP450 3A4/3A5 and 2B6 enzymes in the liver. The 4-hydroxy metabolite spontaneously liberates acrolein, which is excreted in high concentrations in the urine. Acrolein causes a direct irritation of the bladder mucosa, leading to urotoxicity. Both ifosfamide and cyclophosphamide can produce cystitis, which ranges from mild-to-severe bladder damage and hemorrhage. Cystitis is characterized by tissue edema and ulceration followed by sloughing of mucosal epithelial cells, necrosis of smooth muscle fibers and arteries, and culminating in focal hemorrhage.

Clinical presentation

Patients with acrolein-induced hemorrhagic cystitis may have initial symptoms consistent with urinary tract infection (frequency, urgency, dysuria, and nocturia), as well as microscopic and gross hematuria.[231] The symptoms may subside over a period of several days or weeks after discontinuing the agent. The course of acrolein-induced hemorrhagic cystitis usually is relatively benign, although death from massive refractory hemorrhage has occurred.[232] The primary factors that may predispose J.R. to hemorrhagic cystitis include the dose of ifosfamide he is receiving.

Prevention

Historically, forced hydration was the primary method used to prevent hemorrhagic cystitis in patients treated with cyclophosphamide therapy. Theoretically, hydration flushes the toxic acrolein metabolite out of the bladder so that insufficient contact time is available to set up the tissue reaction. The more urotoxic agent, ifosfamide, was introduced to the market with a uroprotective agent, mesna. This agent contains a free thiol group, which can neutralize acrolein in the bladder. When administered in an appropriate dosing

schedule, mesna can prevent bladder toxicity completely. Concurrent use of mesna with ifosfamide is the standard of care.[219,232]

The ASCO guidelines recommend a parenteral mesna dose of 20% of the ifosfamide dose given at 0, 4, and 8 hours after ifosfamide (for a total mesna dose of 60% of the ifosfamide dose).[41] The goal is to maintain prolonged mesna concentrations within the urinary tract that are uroprotective. Repeated administration is required because mesna has a much shorter elimination half-life (<1 hour) than does ifosfamide. If patients receive a continuous infusion of ifosfamide, a different dosing strategy for mesna is required. To prolong mesna's protective effects, ASCO guidelines recommend an IV bolus mesna dose that is 20% of the ifosfamide dose, followed by a mesna continuous infusion that is an additional equivalent of 40% given during and for 12 to 24 hours after the end of the ifosfamide infusion.[41] This regimen ensures that mesna remains in the bladder for an extended amount of time after the end of the ifosfamide infusion.

Various other mesna dosing schedules are clinically used, but no trials have compared the different regimens. Many clinicians use a 1:1 mg dose of mesna to ifosfamide when administered by continuous infusion. The dosing guidelines become less well defined, however, when patients receive higher dosages of ifosfamide (>2.5 g/m^2). The lack of data and the unique pharmacokinetic properties of ifosfamide have caused concerns about the current dosing guidelines. The pharmacokinetics of ifosfamide are nonlinear. For example, the elimination half-life associated with doses of 2.5 g/m^2 is 6 to 8 hours, whereas with doses of 3.5 to 5 g/m^2, it is 14 to 16 hours. The current recommendations for mesna administration enable protection for ~12 hours after an IV bolus; thus, with higher dosages of ifosfamide, mesna should be infused beyond the recommended 8 hours to maintain bladder protection.[232] To ensure maximal protection against urotoxicity, ASCO currently recommends more frequent or prolonged mesna dosage regimens to account for its short half-life.[41] Ifosfamide and mesna are compatible in solution and can be infused together.

Mesna is usually given IV, but an oral formulation is available. The oral bioavailability of mesna is ~50%; therefore, patients should receive twice the standard IV dose (eg, oral mesna 40% of the IV ifosfamide dose) 2 hours before and 4 and 8 hours after ifosfamide.[233] Others have recommended that an oral dose also be given with the ifosfamide dose. Many centers administer the first dose of mesna IV followed by oral doses at 4 and 8 hours, particularly in the outpatient clinic setting.[41]

All patients receiving cyclophosphamide should receive saline diuresis or forced saline diuresis to protect urothelial tissue. When patients receive cyclophosphamide for an HCT, it is at a high dose; therefore, they receive mesna and forced saline diuresis. Other practices to prevent this complication include hyperhydration and the use of continuous bladder irrigation. Data comparing these methods are controversial and report varying rates of hematuria and severe hemorrhagic cystitis. These recommendations are currently supported by the ASCO consensus guideline[41] (see Chapter 101, Hematopoietic Stem Cell Transplantation). J.R. will receive mesna at a dose of 20% of the ifosfamide dose given immediately before ifosfamide, and at 4 and 8 hours after ifosfamide (for a total mesna dose of 60% of the ifosfamide dose).

Treatment

Case 94-10, Question 3: If J.R. exhibits hemorrhagic cystitis, how should it be treated?

Despite preventive strategies, hemorrhagic cystitis may still develop. In these cases, aggressive measures may be needed, including surgical intervention.[232,234]

PULMONARY TOXICITIES

Bleomycin and other agents

CASE 94-11

Question 1: J.A., a 54-year-old male with stage III Hodgkin lymphoma has received ABVD (doxorubicin 25 mg/m^2 IV days 1 and 15, bleomycin 10 units/m^2 IV on days 1 and 15, vinblastine 6 mg/m^2 IV on days 1 and 15, and dacarbazine 375 mg/m^2 IV on days 1 and 15) for six cycles. He presents to the clinic 6 months after his last cycle with dyspnea, a nonproductive cough, and fever. Chest radiograph showed diffuse bilateral infiltrates; his respiratory rate was 36 breaths/minute; and his arterial blood gases (ABGs) were as follows:

pH, 7.50
P_{O_2}, 62 mm Hg
P_{CO_2}, 28 mm Hg
O_2 saturation, 92%

What are the possible causes of his new pulmonary findings?

J.A. is at risk for several processes that could produce diffuse pulmonary infiltrates and dyspnea. He is immunosuppressed secondary to his lymphoma and the chemotherapy; therefore, J.A. has an increased risk of infection and may have pneumonia. In addition, the infiltrates may represent a relapse of his disease or a toxicity from one or more of the cytotoxic agents he received. Further diagnostic workup is necessary to establish the cause.

Case 94-11, Question 2: A bronchoscopy with bronchoalveolar lavage and a biopsy with pathologic and microbiologic evaluations were performed. Bacterial, fungal, and viral culture findings were negative, and the biopsy revealed inflammation and fibrosis with no evidence of lymphoma. These results are highly suggestive of chemotherapy-induced pulmonary damage. Which of the agents that J.A. received is associated with pulmonary toxicity?

J.A. has received bleomycin and that places him at risk for pulmonary toxicity. As part of the initial workup before initiating chemotherapy with ABVD, J.A. had pulmonary function tests done, which were normal. Many additional agents are responsible for pulmonary toxicity including mitomycin, anthracyclines, alkylating agents, platinums, carmustine, bortezomib, carfilzomib, idelalisib, duvelisib, taxanes, and trastuzumab deruxtecan. Many chemotherapy agents have been associated with pulmonary toxicity,

and the varying types of mechanisms and clinical presentations have been reviewed.[235–245] Several reviews discuss the different types of pulmonary toxicities associated with anticancer agents.[235–237,246,247]

Among all chemotherapy agents, bleomycin is associated with the highest incidence of pulmonary toxicity. Although several types have been reported, the most frequent is interstitial pneumonitis followed by pulmonary fibrosis.[235,240,244] Patients generally present with a nonproductive cough and dyspnea. Clinicians may detect only fine crackling bibasilar rales that often progress to coarse rales. The chest radiograph may be normal in the early stages, but patients can exhibit bilateral alveolar and interstitial infiltrates. ABGs show hypoxia, and pulmonary function tests generally reveal a decrease in the diffusing capacity without a significant decrease in the forced vital capacity.[240,244] The most significant factor associated with the development of pulmonary toxicity is the cumulative dose of bleomycin. At total doses <400 units, <10% of patients experience pulmonary toxicity. When the cumulative dose reaches 450 to 500 units, the incidence is higher. A rarer, hypersensitivity reaction produces fever, eosinophilia, and diffuse infiltrates, which is not dose related. The mortality associated with bleomycin pulmonary toxicity is about 50%.[235,244] If bleomycin is discontinued while symptoms are minimal and before pulmonary function has decompensated significantly, the damage may not progress. Other anticancer agents can potentially exacerbate the pulmonary toxicity associated with bleomycin. J.A.'s pulmonary findings are most likely suggestive of bleomycin toxicity. Unfortunately, there are no methods for reversing the pulmonary toxicity seen with bleomycin, and treatment consists of supportive measures such as oxygen and steroids.

Case 94-11, Question 3: Why are routine pulmonary evaluations indicated in patients such as J.A. who receive bleomycin or other pulmonary toxic agents?

Dose-related decreases in diffusing capacity can occur before the onset of clinical symptoms; therefore, routine baseline and serial pulmonary function studies are recommended.[240] Bleomycin therapy

should be withheld if the diffusing capacity falls to <40% of the baseline value, if the forced vital capacity falls to <75% of the baseline value, or if patients exhibit any signs or symptoms of pulmonary damage.[235,244] Some practitioners also recommend limiting the total cumulative lifetime dose to ≤400 units. Specific screening is not routinely recommended for patients receiving other pulmonary toxic agents; however, if patients exhibit any symptoms or clinical findings, therapy should be withheld until the cause can be determined. J.A. underwent pulmonary function tests before his first cycle of ABVD. Further tests are usually not conducted unless the patient shows signs or symptoms of SOB or difficulty breathing. J.A. did not receive any further studies during his chemotherapy courses because he had no pulmonary symptoms until 6 months after his six cycles of ABVD.

Case 94-11, Question 4: How should J.A.'s bleomycin-induced pulmonary toxicity be managed?

If pulmonary toxicity becomes evident, all suspected agents should be discontinued, and the patient should receive symptomatic support based on their physical condition. Other treatable causes of pulmonary infiltrates (eg, infection) should be considered. Often, pulmonary toxicity is irreversible and progressive, and effective treatments are unavailable. Corticosteroids are administered but are most effective in cases of hypersensitivity-associated pulmonary damage. Nevertheless, because other effective treatments are lacking, a trial of steroids generally is indicated for all patients; if steroids are discontinued, they must be tapered carefully to avoid clinical deterioration.

HEPATOTOXICITY

CASE 94-12

Question 1: J.D., a 56-year-old male, has received two courses of therapy with cytarabine for acute myeloid leukemia (AML). Before his therapy was started,

his liver function tests (LFTs) and coagulation studies were within normal limits. His current laboratory values on day 10 of his second cycle of high-dose cytarabine include the following:

Aspartate aminotransferase, 204 units/L
Alanine aminotransferase, 197 units/L
Lactate dehydrogenase, 795 units/L
Alkaline phosphatase, 285 units/L
Bilirubin, 1.2 mg/dL

Could cytarabine be responsible for J.D.'s laboratory abnormalities?

Elevated LFTs occur frequently in patients with cancer and may result from many causes including liver involvement of the tumor (primary or metastatic), hepatotoxic drugs (including those for supportive care such as antimicrobials), infection, parenteral nutrition, and hepatic thrombosis. Other signs and symptoms of hepatotoxicity include jaundice, nausea, vomiting, abdominal pain, and, rarely, encephalopathy. Patients should receive a thorough workup to determine whether they require immediate attention for tumor involvement of the liver or possible infection. In addition, patients should discontinue any nonessential medications that can potentially cause hepatotoxicity. The clinician may also discontinue chemotherapy if this is the suspected cause.

Several anticancer agents, including cytarabine, have been associated with hepatocellular damage (**Table 94-7**).[248–259] Other common agents include asparaginase, carmustine, cytarabine, mercaptopurine, methotrexate, irinotecan, oxaliplatin, clofarabine, imatinib, pazopanib, and idelalisib. A review of 537 patients with cancer and tyrosine kinase–associated liver enzyme elevations showed that clinically significant abnormalities were unusual and transient.[260] Multiple agents have boxed warnings regarding potential hepatotoxicity. The onset of hepatotoxicity with these drugs is usually within 2 months of treatment initiation and is reversible in the majority of cases. Although death from hepatotoxicity in these cases is uncommon, there have been reports of cirrhosis.[260] All of these drugs come in contact with the liver by entering its blood supply; the liver uniquely receives a dual blood supply from the portal and

superior mesenteric veins. The liver detoxifies or inactivates noxious substances and metabolizes many anticancer agents. The exact mechanisms by which cytotoxic and targeted agents cause hepatotoxicity are unknown, but most agents probably cause it by (a) interfering with the mitochondrial function of the hepatocyte, (b) depleting hepatic glutathione stores, (c) eliciting hypersensitivity reactions, (d) decreasing bile flow, or (e) causing phlebitis of the central hepatic vein to produce sinusoidal obstructive syndrome (also known as veno-occlusive disease). Several articles serve as excellent resources for anticancer therapy–induced hepatotoxicity.[248,249,261]

Table 94-7
Hepatotoxicity From Select Antineoplastic Drugs

Drug	Type
Asparaginase[258]	Hepatocellular fatty metamorphosis
Busulfan[259]	Veno-occlusive disease
Carmustine[256]	Hepatocellular
Clofarabine[261]	Hepatocellular
Cytarabine[262]	Cholestatic
Etoposide[263]	Hepatocellular
Imatinib[257]	Hepatocellular
Mercaptopurine[265]	Cholestatic and hepatocellular
Methotrexate[266]	Hepatocellular
Streptozocin[267]	Hepatocellular

Laboratory tests can serve as indicators of liver structure and function. Serum transaminases, alkaline phosphatase, and bilirubin levels should be monitored routinely in patients receiving hepatotoxic chemotherapy. Although these laboratory indices are sensitive, they are nonspecific for the type of liver disease and do not necessarily correlate with hepatic function. Serum levels of proteins produced by the liver (eg, ferritin, albumin, prealbumin, or retinol-binding protein)

also may be helpful in assessing liver function. The decision to continue or discontinue chemotherapy in patients with apparent hepatic dysfunction can be difficult. If the chemotherapy is the suspected cause, therapy should be withheld until LFTs are within normal ranges. The clinician should also consider alternative (nonhepatotoxic) chemotherapy for future treatment. In addition, concomitant agents that are cleared predominantly via the liver may require dose adjustments and should be administered cautiously (**Table 94-8**). High-dose cytarabine is likely responsible for J.A.'s elevated liver enzymes. Therefore, costly workup should be deferred to allow recovery of liver function. Recovery should occur within 2 weeks of chemotherapy. If full recovery does not occur, further therapy (agents, doses, or both) may require modifications.

Table 94-8
Select Anticancer Agents[a] Requiring Dose Modification in Hepatic Dysfunction

Fluorouracil	Methotrexate
Daunorubicin	Paclitaxel
Docetaxel	Vinblastine
Epirubicin	Vincristine
Etoposide	

[a]The agents listed in this table are examples and are not meant to be an exhaustive list of agents that may need dose adjustments. In addition, specific dose reductions may depend on multiple factors including treatment goals (curative vs palliative), performance status, and specific protocols.

LONG-TERM COMPLICATIONS OF ANTICANCER THERAPY

Secondary Malignancies After Anticancer Therapy

CASE 94-13

QUESTION 1: T.D., a 55-year-old female, was diagnosed with an early-stage breast cancer and successfully treated with radical mastectomy followed by four cycles of adjuvant doxorubicin 60 mg/m^2 IV on day 1 with cyclophosphamide 600 mg/m^2 IV on day 1. Eighteen months after her breast cancer therapy was completed, T.D. presents to her primary care physician with fatigue, SOB, easy bruising, and sinusitis. A peripheral blood smear shows a WBC count of 120,000 cells/μL with a differential including >90% leukemic blasts, and a bone marrow biopsy confirms AML. Subsequent cytogenetic analysis revealed abnormalities involving chromosome 11q23.

What factors support the diagnosis of anticancer therapy– associated acute leukemia in T.D.?

Acute leukemia has been associated with cytotoxic therapies used to treat hematologic malignancies, solid tumors, and nonmalignant diseases.[262] It is generally reported after combination chemotherapy that involves topoisomerase inhibitors, including etoposide and anthracyclines.[263] These leukemias, called *therapy-related myeloid neoplasms (tMNs)*, usually occur 1 to 3 years after the completion of chemotherapy, and myelodysplasia does not usually occur before the leukemia. Other characteristics include chromosomal abnormalities involving chromosome 11q23.[262] This challenge is an important area for research given the widespread use of these agents for many curable diseases such as Hodgkin lymphoma, breast cancer, and testicular cancer. AML has also been reported in patients who have had previous exposure to alkylating agents. It usually occurs 5 to 7 years after the patient finishes chemotherapy. Myelodysplastic syndrome (preleukemia changes) commonly occurs in 50% of patients before overt acute leukemia with these agents.

Clonal hematopoiesis of indeterminate potential (CHIP) has been described as a risk factor for the development of tMN; patients with CHIP have underlying changes in the bone marrow that appear to predispose them to tMN upon exposure to chemotherapy.[264] Several

additional factors may increase a patient's risk of exhibiting acute leukemia.[262]

Evidence that cytotoxic agents can cause secondary lymphoid malignancies, particularly non-Hodgkin lymphoma, is also strong. Immunosuppression from the disease and its treatment, rather than the particular agent, may be the primary cause of non-Hodgkin lymphoma. Other secondary malignancies can occur after anticancer treatment as well. Superficial bladder cancer has been reported in patients treated with daily oral cyclophosphamide, and bone sarcoma has occurred after treatment with alkylating agents.[265,266] The secondary solid tumors in patients treated with other cytotoxic agents are considered coincidental.

T.D.'s AML probably occurred secondary to her previous doxorubicin. The chemotherapy agent, as well as the time course for her acute leukemia, is consistent with topoisomerase-II agent-induced malignancies. Although initial trials indicated a risk of myelodysplastic syndrome and AML of 0.27% at 8 years after adjuvant chemotherapy for breast cancer, a large retrospective review of an NCCN database showed a risk of 0.24% at 5 years and 0.48% at 10 years, for both myeloid and lymphoid malignancies, and was largely related to chemotherapy rather than to surgery or radiation therapy.[267] In addition, cytogenetic abnormalities occur in >90% of those patients who have received chemotherapy or radiation therapy and have subsequently experienced therapy-related myelodysplastic syndrome or AML.[262] Abnormalities in chromosome 11q23 are involved in many of the cases with cytogenetic abnormalities from topoisomerase inhibitors.[262] The chromosomal abnormalities of 11q23 in T.D. strongly support the diagnosis of chemotherapy-associated acute leukemia rather than of de novo leukemia.

Case 94-13, Question 2: Are the therapy and prognosis of T.D. with treatment-associated AML similar to those of patients with de novo AML?

Chemotherapy is much less effective for the treatment of tMN than is de novo AML. Complete remissions with standard cytarabine and daunorubicin regimens are achieved in less than half of patients with treatment-associated AML compared with a complete remission rate of 70% to 80% in patients with de novo AML[262] (see Chapter 96, Adult Hematologic Malignancies).

Mutations in TP53 are common in tMN and are associated with resistance to chemotherapy and poor prognosis.[268] The overall survival estimate for patients with tMN is about 8 to 10 months.[269]

The best "treatment" of therapy-associated AML is prevention. In patients such as T.D. receiving adjuvant chemotherapy for a curable malignancy, avoiding the use of agents that cause treatment-related AML should be discussed in conjunction with the benefits of therapy. Use of alternative regimens and avoidance of chemotherapy altogether is increasing as more is learned about secondary leukemias and effective management of malignancies with chemotherapy-sparing approaches.

Fertility and Teratogenicity

Effects on Oogenesis

CASE 94-14

QUESTION 1: C.L., a 32-year-old female with recently diagnosed stage II breast cancer, underwent a lumpectomy and external beam radiation therapy and is scheduled to begin adjuvant chemotherapy with doxorubicin and cyclophosphamide followed by paclitaxel (AC-T). C.L. was married 12 months before her diagnosis and wishes to have children.

What are C.L.'s prospects for fertility after adjuvant chemotherapy?

Cytotoxic chemotherapy is potentially gonadotoxic in humans. Ovarian biopsies taken from females treated for cancer demonstrate loss of ova and follicular elements. This injury is evident even in prepubertal female patients treated for cancer. Ova die or become nonfunctional by direct injury to the ova or by indirect injury resulting

from loss of supporting follicular cells. If the damage to the follicular elements is extensive and irreversible, fertility is impaired even if the ova are spared.

Agent-induced injury to ova and follicular elements reduces ovarian estrogen and progesterone secretion in menstruating females. This causes the hypothalamus and pituitary to secrete more follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which in turn increase follicular recruitment and the number of follicles vulnerable to cytotoxic chemotherapy agents. If the gonadal toxicity is severe or prolonged, permanent ovarian failure can occur secondary to depletion of ova and follicles. Recovery of some of the affected follicles can occur and is manifested by irregular menses or delayed recovery of menses. If the ova are spared and follicular cells recover sufficiently, ovulation and pregnancy might occur, but premature ovarian failure is inevitable in most females treated with large doses of gonadotoxic agents given for long periods.[270]

Prepubertal girls have a greater reserve of primary follicles. Because their ovaries are not producing estrogen and progesterone, increases in FSH and LH with resultant recruitment of follicular elements do not occur. For this reason, prepubertal girls can tolerate large doses without apparent effects even if the pathology previously described occurs. The gonadal effects of cytotoxic chemotherapy in females have been described in several reviews.[270–272]

C.L. is going to receive an alkylating agent, which are the most potent gonadotoxic agents. Cyclophosphamide is well known for producing infertility in males and females and gonadal failure even in children. This effect is influenced strongly by the total dose of cyclophosphamide and the patient's age at the onset of chemotherapy. Nearly 100% of females older than 20 years of age experience amenorrhea when the mean total dose is 20 to 50 g. The same consequence can be expected in females older than 35 years of age who receive >6 to 10 g and in females 45 years of age and older who receive >5 g.[273] Depending on the exact dose of cyclophosphamide in the AC-T regimen planned, C.L. may or may not fall into a dose range that would be expected to produce permanent amenorrhea.

The clinician also must consider that a synergistic gonadotoxic effect has been reported when doxorubicin is combined with cyclophosphamide. Aside from the alkylating agents, other agents with strong evidence of gonadal toxicity include platinums, anthracyclines, vinblastine, and etoposide. Several resources discuss the doses of chemotherapy agents, used both alone and in combination, and specific incidences of associated gonadotoxicity, as well as the prevalence of temporary and permanent amenorrhea.[271,273,274]

C.L. most likely will experience amenorrhea along with the signs and symptoms of menopause because both estrogen and progesterone production diminishes during cytotoxic chemotherapy. C.L. may recover from chemotherapy-induced amenorrhea months to years after completion of her therapy. Recovery may be manifested as amenorrhea interspersed with normal menstrual periods.

Pregnancy is possible during periods of normal menstruation because ovulation does occur in most instances. However, premature menopause is likely. Because the greatest risk of pregnancy exists early in the course of therapy, and because ovulation may occur despite amenorrhea, C.L. should be counseled to practice birth control while receiving cytotoxic chemotherapy. Because hormonal contraceptives are contraindicated in patients with breast and liver cancer, barrier methods (ie, diaphragm, condoms, and spermicide) or copper intrauterine devices should be advised.[275] Consensus guidelines are available; however, evidence and recommendations are lacking for certain cancer types, such as leukemia, lymphoma, and bone tumors.[276,277] Methods to preserve fertility after chemotherapy for females include cryopreservation of embryos or unfertilized oocytes, and ovarian tissue transposition, for which further recommendations are published by ASCO.[278]

EFFECTS ON SPERMATOGENESIS

CASE 94-15

QUESTION 1: J.K., a 25-year-old male with recently diagnosed testicular cancer, will receive systemic chemotherapy with bleomycin, etoposide, and cisplatin. What effect does systemic chemotherapy have on male gonadal function?

The primary gonadal toxic effect of cytotoxic chemotherapy agents in male patients is a progressive dose-related depletion of the germinal epithelium lining the seminiferous tubule. This leads to a marked reduction in testicular volume and azoospermia. The Leydig cells responsible for testosterone production remain morphologically intact, although mild functional impairment occurs rarely. The major toxicity of chemotherapy in males is loss of reproductive capacity. During treatment, libido and sexual activity may decline, but most males report a return to pretreatment sexual function after chemotherapy.[245]

Of the cytotoxic chemotherapy agents, alkylating agents are associated most commonly with azoospermia. Progressive dose-related oligospermia occurs in males receiving chlorambucil,[279,280] cyclophosphamide,[281,282] melphalan, busulfan, procarbazine, and nitrosoureas; procarbazine appears to be the most gonadotoxic alkylating agent in males. Doxorubicin, vinblastine, cytarabine, and cisplatin also have been associated with azoospermia,[283] and doxorubicin appears to have a synergistic toxic effect in males when given with cyclophosphamide. Phase-specific agents, such as antimetabolites and vinca alkaloids, seem unlikely to produce azoospermia when used alone, but may play a minor role in combination chemotherapy regimens.[284]

In contrast to oogenesis, in which females are born with a full complement of ova, spermatogenesis occurs in a continuous cycle of regeneration, differentiation, and maturation beginning in the second month of embryogenesis and continuing through old age. Gonadotoxic agents generally are used in sufficiently large doses to affect varying proportions of maturing sperm cells in any stage of development. Because spermatogenesis must restart at the beginning after agent-induced azoospermia occurs, the length of recovery is prolonged, usually lasting at least 2 to 3 years. The

relationship of age to the development of azoospermia is far less clear than is the relationship of age to ovarian suppression. Although prepubertal boys are less likely to be affected by chemotherapy agents than are adult males, the reserve of primitive sperm cells in male children is far less than it is in adults. Therefore, the spermatogenesis potential in prepubertal testes may make them more vulnerable to cytotoxic damage than that in those of adults. A review of the literature regarding the effects of cytotoxic chemotherapy administered to male children concluded that agents and regimens known to be toxic in males should be considered toxic in young boys.[245,274] In adult survivors of childhood cancer treated with alkylating agents, azoospermia was present in 25% of patients, oligospermia in 28%, and normospermia in 48%. Impaired spermatogenesis was unlikely up to a cyclophosphamide equivalent dose of 4000 mg/m^2. Sperm motility and morphology may also be affected.[285] Short of a testicular biopsy, the damage cannot be detected until puberty.

The two diseases most likely to affect the fertility of young males are Hodgkin lymphoma and testicular cancer. The standard treatment for advanced Hodgkin lymphoma is ABVD. Azoospermia has been observed in 35% of patients receiving ABVD, and spermatogenesis nearly always recovered in these patients.[283] Evidence to date suggests that therapy-induced azoospermia following treatment with vinblastine, bleomycin, and cisplatin for nonseminomatous testicular carcinoma is reversible within 2 to 3 years in ~50% of patients treated. Those who recover spermatogenesis are capable of impregnating their female partners.[286,287] In this particular patient population, it is important to recognize that retroperitoneal lymph node dissection, which often results in retrograde ejaculation, as well as cryptorchidism, which predisposes to infertility, may contribute to the lack of full recovery of fertility potential.

Case 94-15, Question 2: Aside from the use of anticancer therapy agents with less gonadal toxicity, are there means of circumventing infertility in young patients such as J.K. receiving therapy?

Sperm or gamete cryopreservation should be considered in males. A major limitation of this approach has been the finding of diminished sperm counts, sperm volume, and sperm motility in young males affected with Hodgkin lymphoma and testicular cancer even before combination chemotherapy is initiated. Although published studies suggest that the quantity and motility of sperm are important determinants of successful artificial insemination, pregnancies have been reported. Thus, sperm banking should be considered even in oligospermic males.[245,284] Oocyte cryopreservation and embryo cryopreservation now are feasible options for young females about to undergo cytotoxic chemotherapy. Even in the face of cytotoxic chemotherapy-induced ovarian failure, in vitro fertilization of an ovum and implantation into the endometrium with proper hormonal support can successfully accommodate a term pregnancy. This may be an option for females.[272,278]

In both sexes, it has been hypothesized that gonadal toxicity from cytotoxic chemotherapy could be decreased by inhibiting spermatogenesis or follicular development during therapy. There is currently no evidence to support hormonal gonadoprotection in males. There is mixed evidence to support administration of gonadotropin-releasing hormone agonists to preserve fertility in females. Methods used to suppress gonadal function have included administration of testosterone in males, oral contraceptives in females, and gonadotropin-releasing hormone analogs in both males and females. Several reviews describe these approaches in detail,[245,271,272] and ASCO provides recommendations on preserving fertility in patients with cancer.[278]

TERATOGENICITY

CASE 94-15, QUESTION 3: If J.K. regains fertility after his planned combination chemotherapy regimens, is he at risk for producing offspring with congenital abnormalities or an excess risk of cancer?

Most of the agents used to treat cancer are designed specifically to interfere with DNA synthesis, cellular metabolism, and cell division. Thus, reason exists to suspect that they may cause mutation of ova or spermatocytes exposed to these effects. Outcomes of pregnancies in survivors of cancer are published as case reports, small series, and retrospective case series. Nearly 1600 children have been born to 1078 patients previously treated for malignancy in childhood or as adults. From this, there is no evidence that spontaneous abortion, genetic disease, or congenital anomalies occur more frequently in the progeny of cancer survivors. Similarly, there does not appear to be an increased risk of malignancy in the offspring of patients treated for cancer.[274] The likely explanation for this is that ova and sperm cells affected by cytotoxic chemotherapy usually are killed. The risk of producing an abnormal offspring thus would be highest at the time of chemotherapy. Males and females should be explicitly discouraged from conception during chemotherapy. In general, adults surviving cancer should be advised to wait at least 2 years after completion of therapy before attempting conception. This also provides time to assess the likelihood of the necessity for further treatment that would have grave consequences on the fetus, particularly in the case of female patients.

Pediatric Malignancies

M. Brooke Bernhardt and Nicole A. Kaiser

CORE PRINCIPLES		CHAPTER CASES
1	When monitoring therapy in children, it is important to remember the age-related differences in measured parameters for vital signs, developmental changes, and variability in expected values from infancy to adulthood. Blood pressures are lower and heart rates and respirations are higher in younger children. Intake and output need to be considered in relationship to the patient's size. Calculations for estimations of glomerular filtration rate are different than those used in adults.	**Case 95-1 (Questions 3, 4)**

CORE PRINCIPLES		CHAPTER CASES
2	Infants have larger body surface area–weight ratios than older children. Further, organ function changes rapidly during the first year of life. Therefore, chemotherapy dosing guidelines in protocols generally specify how to calculate doses for smaller children and infants (ie, converting to mg/kg dosing from mg/m^2, or halving doses).	**Case 95-2 (Question 2)**
3	Leucovorin, when used with methotrexate, reduces methotrexate-related toxicities to rapidly proliferating cells. In treating children with high-dose methotrexate and leucovorin rescue, serum methotrexate concentrations are measured so that leucovorin will be discontinued at the correct time. Renal dysfunction, fluid accumulation in the patient, or drug interactions can slow methotrexate excretion and require prolonged leucovorin rescue.	**Case 95-3 (Questions 3, 4)**

CORE PRINCIPLES		CHAPTER CASES
4	Rhabdomyosarcoma is a soft tissue tumor of skeletal muscle origin, and it is the most common soft tissue sarcoma of childhood, occurring in 3% of all children with cancer. The two most common histologic types in children are embryonal and alveolar. Using the combination of vincristine, dactinomycin, and cyclophosphamide with local control of surgery or radiation, it is associated with an ~75% failure-free survival for patients with nonmetastatic disease.	**Case 95-4 (Question 1)**
5	Acute lymphoblastic leukemia (ALL) involves replacement of normal bone marrow elements because of abnormalities in cellular proliferation. Signs and symptoms relate to the deficiency in normal bone marrow elements.	**Case 95-5 (Question 1)**
6	Important prognostic variables in ALL are based on clinical and laboratory findings, including age and white blood cells at diagnosis, immunologic classification, cytogenetics, and minimal residual disease (MRD) evaluation on bone marrow.	**Case 95-5 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
7	The treatment of ALL is divided into phases, including remission induction therapy, central nervous system (CNS) preventive therapy, consolidation/intensification phases, and maintenance therapy. All phases are different, each using multiple agents, schedules, and toxicity.	**Case 95-5 (Questions 2, 3, 5, 6, 9–11)**
8	CNS preventive therapy is a key component of ALL treatment. Contemporary treatment/preventive regimens are composed of intrathecal administration of antimetabolite chemotherapy. CNS radiation is reserved for special situations.	**Case 95-5 (Questions 4, 5, 7, 8)**
9	Patients with relapsed ALL will often achieve a second remission of their disease but have a high likelihood of further relapses. Various approaches, including intensified chemotherapy, targeted agents, or stem cell transplantation, have been used in the treatment of relapse.	**Case 95-6 (Questions 1–3)**

CORE PRINCIPLES		CHAPTER CASES
10	Non-Hodgkin lymphoma accounts for 10% of childhood cancers. It has a cure rate of more than 80%. It often presents as a mass in the mediastinum or as pleural effusions. Masses may be large; therefore, adjunctive therapies to prevent tumor lysis syndrome and nephropathy are necessary.	**Case 95-7 (Question 1)**

INTRODUCTION

In the United States, cancer is the leading cause of disease-related death for children between ages 1 and 14 years.[1] About 11,000 children younger than age 15 years are diagnosed with cancer each year, and around 85% of them can anticipate long-term survival.[1] Acute leukemias are the most common malignancies of childhood; the selected solid tumors discussed in this chapter each represent 2.5% to 7.0% of all childhood malignancies.[1] Many common pediatric solid tumors are uncommon in adults. Likewise, many tumors common in adults occur infrequently in children. In general, sarcomas and embryonal tumors are common in children, whereas carcinomas predominate in adults.

Genetics

Similar to adult cancers, the association of many pediatric cancers with chromosomal aberrations or genetic defects is well-confirmed. Examples include the association of Wilms tumor with congenital malformations, acute leukemias with Down syndrome, and the association of some pediatric cancers with loss of the p53 or retinoblastoma tumor suppressor genes.[2–7]

Carcinogens and Exposures

The role of carcinogens in pediatric cancer is probably less prominent than in adults because of the long latency periods required. Carcinogens and other exposures are implicated in the etiology of some childhood cancers.[8] Maternal use of diethylstilbestrol during pregnancy is associated with an increased risk of vaginal or cervical cancer in offspring.[6] Other prenatal exposures, such as maternal infection, pesticide exposure, and paternal smoking, may also contribute to increased childhood cancer risk.[9–11] Postnatal exposure to ionizing radiation, including exposure through medical diagnostic imaging, is associated with an increased risk of multiple types of childhood cancer and should be minimized.[12] Long-term survivors of childhood cancer are at a significantly increased risk of secondary malignancy, a risk that continues for at least 20 years following initial diagnosis.[8,13,14]

Patient Age

As with adult patients, patient age at diagnosis can be a factor in prognosis and treatment response. Neuroblastoma is the most common malignancy in infants; survival is typically excellent in infants and toddlers up to 18 months of life, a benefit attributed to the biology of the disease in this age group.[15] In contrast, infants with ALL tend to have a worse prognosis than older children because of the presence of specific genomic features commonly seen in infants with ALL.[16]

Age is also associated with treatment-related toxicities. Younger children are more susceptible to radiation-related toxicities, including radiation-induced disruption in normal bone metabolism, fertility impairment, endocrinopathies, cardiomyopathy, and significant long-term neurocognitive impairment.[17–20] Younger age (<13 years old) at the time of anthracycline administration is associated with a higher risk of a delayed onset of heart failure.[21] Lastly, older age at diagnosis is a recognized risk factor for steroid-induced osteonecrosis in children with ALL.[22]

Adolescents and young adults (AYAs) with cancer are a special population with unique needs.[1] About 90,000 persons in this age group (widely defined as ages 15–39 years) will be diagnosed with cancer in the United States each year. Survival for AYAs with some types of cancer has lagged behind those of younger children and older adults. AYA with cancer may have molecularly distinct disease features, necessitating alternate approaches to therapy.[23,24] Although AYA may be treated at pediatric or adult cancer programs, survival is typically higher in patients treated according to pediatric-based protocols.[25,26] AYAs have other unique age-related needs, including fertility preservation, cancer treatment during pregnancy, and prevention and screening of other cancers.[1]

Multi-Institutional Research Groups

Success in the improvement of survival from childhood cancer is largely attributed to cooperative group clinical trials studied over the past 60 years.[27,28] Most centers treating children with cancer in the United States are members of the Children's Oncology Group (COG), a pediatric multi-institutional research group in the United States, Canada, Australia, and New Zealand, which is sponsored by the National Cancer Institute and many private organizations.[29] Much of the success with improving survival through cooperative group trials is attributed to gains in the treatment of newly diagnosed ALL. Despite this success, relapsed ALL remains the most common cause of death from childhood cancer.[28]

Late Effects

Late effects can be described as toxicities or complications that either persist or occur after therapy is finished. Examples of late effects include joint or bone problems, heart failure, second malignancies, strokes, and cognitive dysfunction.[30] The Childhood Cancer Survivor Study (CCSS) includes data on health problems experienced by thousands of pediatric cancer survivors and a

sample of their siblings. Initial data from the study showed that more than 60% of the survivors had at least one chronic medical problem, and 27% had a severe or life-threatening health problem.[30] The overall relative risk of a health problem compared to siblings was 3.3-fold, with specific risks as high as 54-fold for joint replacements and 15-fold for heart failure. Subsequent analyses of the data are tracked and shared via the CCSS website (www.stjude.org/ccss). This type of knowledge has reemphasized the need for clinicians to limit toxic therapies where possible with the aim of reducing late effects and improving the quality of life for survivors. These and other data have helped inform the evidence-based COG Survivorship Guidelines to help standardize an approach to appropriate screening and management of childhood cancer survivors.[31] All cancer survivors should have access to a record of their treatment history for the remainder of their lives.[32,33] This valuable resource will guide health care professionals as they make evidence-based decisions on long-term follow-up of childhood cancer survivors.

PEDIATRIC SOLID TUMORS

Neuroblastoma

Description, Incidence, and Epidemiology

Neuroblastoma is a tumor that develops from immature cells of the peripheral nervous system.[1] It is the most common extracranial tumor during childhood, representing 6% of all childhood cancers and more than 650 new cases annually in the United States.[1] The median age at diagnosis is 19 months; about 37% of cases occur in children younger than age 1 year and 90% before age 5 years.[1,34] The 5-year survival rate of children with neuroblastoma has increased over time.[35] Lower-risk patients, which mostly includes infants with stage 1, 2, or 4S, may have spontaneous remissions or at least a 75% to >90% 5-year event-free survival.[36] Intermediate-

risk patients have a 50% to 75% event-free survival, and high-risk patients a 19% to 42% 5-year event-free survival.[37] With evolving therapies for high-risk patients, survival rates have seen modest but meaningful improvements.

PATHOPHYSIOLOGY

Neural tumors related to neuroblastoma can be ganglioneuroma (benign) or ganglioneuroblastoma (mixed benign and malignant) or pure neuroblastoma. At biopsy, multiple specimens may be required to fully assess the malignant potential of the tumor. As with other cancers, neuroblastoma results from the loss of cell-growth control because of oncogene activation, tumor suppressor gene inactivation, and related malignant processes. Despite that familial neuroblastoma is relatively rare (only 1%–2% of all cases), several germline mutations and cancer predisposition syndromes have been reported. Patients with these features are at a significantly increased risk of developing neuroblastoma. Specifically, familial neuroblastoma has been associated with *ALK* gene mutations, *PHOX2B* gene mutations, neurofibromatosis type 1, Li–Fraumeni syndrome, Costello syndrome, and Beckwith–Wiedemann syndrome, among others.[38] The American Association for Cancer Research now recommends biochemical and radiographic screening for patients with some of these features within the first 10 years of life.[39]

CLINICAL PRESENTATION, DIAGNOSIS, STAGING, AND OTHER PROGNOSTIC FACTORS

Patients with neuroblastoma often present with a fixed, hard, abdominal mass noted on physical examination by the family or physician, and possibly other signs or symptoms, depending on the location of the primary tumor and metastases. For example, gastrointestinal (GI) fullness, discomfort, or dysfunction can occur. Other less common but characteristic signs include proptosis with periorbital ecchymoses, increased renin hypertension, secretory diarrhea with increased vasoactive intestinal peptide, respiratory

distress, nerve root compression, opsomyoclonus, and unilateral ptosis.[38] The most common sites of metastases are the bone marrow, bone, liver, and skin.[14]

A diagnosis of neuroblastoma includes tumor biopsy, imaging of the primary tumor mass (with computed tomography and/or magnetic resonance imaging [MRI] with contrast), as well as scanning with metaiodobenzylguanidine (MIBG). MIBG is a sensitive evaluation because of its high uptake into the tumor tissue (including metastatic sites), proving useful for diagnosis, staging, and assessment of tumor response to therapy.[40,41] The catecholamine metabolites vanillylmandelic acid (VMA) and homovanillic acid (HVA) are elevated in the urine of 90% of patients with neuroblastoma; although not typically used for diagnosis and staging, they may be useful for evaluation of microscopic or persistent disease.[38] A large number of prognostic factors have been identified based on diagnostic features; these factors are discussed in detail elsewhere.[38] Briefly, the primary prognostic factors can be classified into the following categories: age at diagnosis, tumor histology, biologic features, site of primary tumor, stage of disease, response to therapy, lactate dehydrogenase (LDH) level, and serum ferritin.[38]

The International Neuroblastoma Risk Group Staging System (INRGSS) classifies the surgical stage by the extent of disease at diagnosis, prior to therapy or surgery. The four stages (L1, L2, M, and MS) describe the disease as locoregional (L) versus metastatic (M). The staging also indicates the presence of locoregional image-defined risk factors (IDRFs; L2) versus none (L1); or a diagnosis of “metastatic special” disease (MS: children younger than age 18 months with metastases confined to the skin, liver, and/or bone marrow) versus others with metastatic disease (M).[42,43]

The classification of favorable versus unfavorable genomics is a field of rapid change and critically important to accurate staging of the disease. Currently, favorable genomic features include the following: hyperdiploid neuroblastoma cells without segmental copy number aberrations, including no loss of copy number at 1p, 3p, 4p, or 11q and no gain of copy number at 1q, 2p, or 17q.[38] Each patient is assigned a “risk stage” (low, intermediate, or high risk) at

diagnosis based on their INRGSS, IDRFs, and biologic/genomic risk factors; this risk stage is predictive of the risk of relapse and, thus, drives treatment decisions. Most low- and intermediate-risk neuroblastomas occur in children younger than 18 months old at diagnosis; typically, these tumors may be hyperdiploid and have gains of whole chromosomes.[36,44] Overall survival (OS) for patients at low- and intermediate risk is excellent, at 97% (5-year OS) and 96% (3-year OS), respectively.[15,45,46] Unfortunately, survival for patients at high risk is still a challenge, with 3-year event-free survival around 50%.[38,47]

OVERVIEW OF TREATMENT

In current U.S. clinical trials, patients with low-risk disease are typically treated with surgery followed by observation (**Table 95-1**). Some patients at low risk may receive observation only (perinatal neuroblastoma, small adrenal tumors), chemotherapy with or without surgery (symptomatic disease or unresectable disease following surgery), or radiation (emergently, based on tumor location). Two to four courses of chemotherapy may be used with initial surgery if organ-threatening symptoms are present. Intermediate-risk disease is treated with surgery and four to eight courses of chemotherapy (**Tables 95-1** and **95-2**) for favorable or unfavorable histology and ploidy.[38,45] Patients with low-risk and intermediate-risk disease should receive chemotherapy, which avoids agents with significant long-term toxicities, when possible, given the high rate of survival. For example, most regimens for these patients avoid cisplatin to reduce nephrotoxicity and ototoxicity, limit the total doxorubicin dose to avoid cardiac toxicity, limit the total etoposide dose to reduce the risk of secondary acute myelogenous leukemia, and avoid ifosfamide to eliminate the risk of Fanconi renal syndrome. Radiation therapy is reserved for poor responders.

Table 95-1
Example of Children's Oncology Group Neuroblastoma Risk

Groups and Treatment for Patients at Low Risk, Intermediate Risk, and High Risk

Low Risk; Surgery and Observation
All stage 1 patients
Patients with stage 2A or 2B, >50% resected and MYCN not amplified[a]
Infants with 4S with MYCN not amplified, favorable histology, and hyperdiploidy
Low Risk, Group 2; Receive Two Cycles of Chemotherapy With Surgery
Stage 2A/2B, >50% resected, or biopsy only and MYCN not amplified
Infants with stage 3 or symptomatic 4S, MYCN not amplified, favorable histology, and hyperdiploid; increase one group if loss of heterozygosity at 1p or 11q
Stage 3, >1 year old, MYCN not amplified, favorable histology
Intermediate Risk, Group 3; Four Cycles of Chemotherapy With Surgery
Infants with stage 3, MYCN not amplified, and diploidy or unfavorable histology
Stage 4, up to 18 months old, MYCN not amplified (good genomics)
Infants with stages 4S and MYCN not amplified, and either diploidy or unfavorable histology
Intermediate Risk, Group 4; Eight Cycles of Chemotherapy With Surgery
Infants with stage 4S, unknown biology
Infants with stage 4, MYCN not amplified, with diploidy or unfavorable histology
Stage 3, up to 18 months old, MYCN not amplified and unfavorable histology
High Risk
Biopsy, five to six cycles of chemotherapy, followed by definitive surgery, high-dose chemotherapy with autologous progenitor cell rescue, radiation to the primary site, and maintenance therapy Induction chemotherapy: vincristine, doxorubicin, and cyclophosphamide for cycles 1, 2, 4, and 6; cisplatin and etoposide for cycles 3 and 5 Consolidation: high-dose chemotherapy (eg, busulfan and melphalan) followed by autologous progenitor cell rescue Maintenance therapy: six cycles of isotretinoin (2 weeks on; 2 weeks off for each cycle) concurrent with five cycles of dinutuximab with GM-CSF[b]
MYCN amplified and not included in previous groups

Note: Consult current protocols as classifications and treatment recommendations are changing rapidly. Typical correlations with the newer staging terminology: L1 and MS patients with good genomics would be in the low-risk group; L2 patients with good genomics would be in the intermediate-risk group but bad genomics in

the high-risk group; MS patients with good genomics would be lower risk or with bad genomics would be high risk; M patients would be in the high risk unless they are <18 months old with good genomics. See Table 95-2 for details of chemotherapy regimens in low-risk and intermediate-risk patients.

[a]*MYCN* is an oncogene that is associated with more aggressive higher-risk neuroblastomas.

[b]GM-CSF is granulocyte-macrophage colony-stimulating factor.

Source: National Cancer Institute. *Neuroblastoma Treatment (PDQ®): Health Professional Version. PDQ Cancer Information Summaries*. Accessed January 5, 2021. https://www.cancer.gov/types/neuroblastoma/hp/neuroblastoma-treatment-pdq.

Table 95-2
Typical Cycles of Chemotherapy Used in Children's Oncology Group Low-Risk and Intermediate-Risk Neuroblastoma

Cycle[a]	Drugs
1	Carboplatin, etoposide
2	Carboplatin, cyclophosphamide, doxorubicin
3	Cyclophosphamide, etoposide
4	Carboplatin, doxorubicin, etoposide
5	Cyclophosphamide, etoposide
6	Carboplatin, cyclophosphamide, doxorubicin
7	Carboplatin, etoposide
8	Cyclophosphamide, doxorubicin

[a]Each row represents a single 21-day cycle of therapy. Generally, the first four cycles are used in patients at intermediate risk with favorable histology disease, and all eight for patients with unfavorable histology. Patients at low risk whose disease is potentially organ-threatening may receive the first two to four cycles plus surgery. See **Table 95-1** for common chemotherapy guidelines for patients with neuroblastoma.

Source: National Cancer Institute. *Neuroblastoma Treatment (PDQ®): Health Professional Version. PDQ Cancer Information Summaries*. Accessed January 5, 2021. https://www.cancer.gov/types/neuroblastoma/hp/neuroblastoma-treatment-pdq.

Therapy for high-risk disease generally involves a first surgery for biopsy, aggressive chemotherapy, second-look surgery for residual

tumor resection (in most patients/centers), tandem cycles of high-dose chemotherapy with autologous progenitor cell rescue, radiation to the tumor bed, and postconsolidation (maintenance) therapy (see Table 95-1).[37,38,48–56] High-dose chemotherapy with autologous progenitor cell rescue improved 5-year disease progression–free survival to 49% from historic values of 10% to 20%; however, relapses can occur later with 7-year disease progression–free survival of only 26%.[57,58] Disease-free survival (DFS) can be further improved (46% vs 29% 5-year postchemotherapy DFS) for patients with high-risk disease if standard-dose or high-dose chemotherapy is followed by maintenance with six cycles of isotretinoin 80 mg/m^2 given orally twice daily for 14 days of each 28-day cycle.[57] Addition of the anti-GD2 monoclonal antibody, dinutuximab, along with interleukin-2 and granulocyte-macrophage colony-stimulating factor (GM-CSF), to the maintenance regimen has been shown to further increase survival.[56,59] Typical conditioning regimens preceding autologous progenitor cell rescue include carboplatin and etoposide with melphalan, or busulfan plus melphalan.[51,60]

CLINICAL PRESENTATION AND DIAGNOSIS

CASE 95-1

Question 1: H.K. is a 2-year-old female with a 3-month history of constipation and progressive abdominal distension. She has a decreased appetite, 1-week history of vomiting, and she is pale and tired. She has a large retroperitoneal mass and multiple bilateral enlarged inguinal lymph nodes. Her white blood cell (WBC) count and differential and platelets are within normal limits. Serum sodium, potassium, chloride, creatinine, and glucose are within normal limits. Her laboratory test results also include the following:

Hemoglobin (Hgb), 5.1 g/dL (normal, 11–14 g/dL)
Lactate dehydrogenase (LDH), 424 units/L
Albumin, 2.3 g/dL
Urine HVA, 570 mg/g creatinine (normal, <26 mg/g)
Urine VMA, 31 mg/g creatinine (normal, <11 mg/g)

Biopsies of the abdominal mass and bone marrow are positive for neuroblastoma cells that are MYCN amplified. The lymph nodes are negative for neuroblastoma. Scans are negative for other sites of disease.

Which of these signs, symptoms, and laboratory results are consistent with a diagnosis of neuroblastoma?

Virtually all of H.K.'s findings are consistent with neuroblastoma. The low hemoglobin and albumin and high LDH, however, are not specific for this cancer. In addition to the biopsy, the elevated urine VMA and HVA are most helpful in confirming the diagnosis of neuroblastoma. In H.K., biopsies of the bone marrow, lymph nodes, and primary tumor were necessary to demonstrate the presence or absence of neuroblastoma at more than one site for staging purposes.

TREATMENT

Case 95-1, Question 2: What stage of disease does H.K. have? What treatment will she receive?

H.K.'s abdominal disease with distant bone marrow involvement indicates metastatic (M) disease. She has unfavorable genomic features, including MYCN amplification. Considering her age and disease stage, H.K. has a high risk of dying from her disease. Therefore, she is started on chemotherapy for high-risk patients consisting of vincristine, doxorubicin, and cyclophosphamide for cycles 1, 2, 4, and 6, and cisplatin and etoposide for cycles 3 and 5.

Case 95-1, Question 3: H.K. is 32.08-inch (81.5-cm) tall, weighs 25.68 pounds (11.65 kg), and has a body surface area of 0.5 m^2. For her third chemotherapy cycle, consisting of cisplatin 50 mg/m^2/day on days 1 through 4 and etoposide 200 mg/m^2/day on days 1 through 3, she is given hydration fluids of 5% dextrose with 0.45% sodium chloride at 62.5 mL/hour. Urine output is 4 mL/kg/hour. How does monitoring of H.K.'s chemotherapy differ from that of an adult?

Monitoring vital signs for etoposide

Although prevention and monitoring of toxicities from chemotherapy agents in children follow the same basic rules as in adults, there are some differences. When monitoring vital signs for hypotensive reactions to etoposide, normal blood pressure will be lower (hypotension is defined as a systolic blood pressure under 74 mm Hg for a 2-year-old girl) and the pulse higher (mean, 119 beats/minute for a 2-year-old) than in adults. It is important to have baseline vital signs so that hypotension or tachycardia will be recognized.

Monitoring hydration for cisplatin

In adults receiving cisplatin, hydration is often standardized to a set volume (eg, 1–2 L) of intravenous (IV) fluids given before the drug, with the drug (another 1–2 L), and then as continuous hydration for at least 24 hours after the dose. In children, hydration volumes should be calculated based on the child's size. To decrease the risk of cisplatin nephrotoxicity, most pediatric protocols recommend IV fluids at twice maintenance rates to maintain urine outputs of at least 2 to 3 mL/kg/hour. The COG calculates maintenance fluids as 1500 mL/m^2 per 24-hour period. As such, H.K. should receive twice that amount for cisplatin hyper-hydration, or 1500 mL during 24 hours (3000 $mL/m^2 \times 0.5\ m^2 \div 24$ hours = 62.5 mL/hour). H.K.'s measured urine output is 4 mL/kg/hour, which should be adequate to prevent nephrotoxicity. Weight should also be monitored throughout cisplatin administration to assure fluid balance. Acute weight gain may require diuretics to prevent fluid overload, but diuretics should be used judiciously to avoid the risk of acute kidney injury.

Adjustment of creatinine clearance in pediatric patients

Case 95-1, Question 4: H.K.'s estimated glomerular filtration rate (eGFR) is 39 mL/minute/1.73 m^2 using the revised/bedside Schwartz equation.[61] Should her cisplatin be withheld, or the dose adjusted because of low creatinine clearance?

Cisplatin is typically avoided in patients with severely impaired renal function. However, H.K. has a disease with a high likelihood of not responding to therapy or resulting in relapse. Therefore, reducing therapy should only be considered when all avenues have been explored. The accuracy of serum creatinine and creatinine clearance in assessing renal function during cisplatin therapy in children has been questioned.[62–64] Therefore, it is recommended to obtain a more precise measurement of glomerular filtration, such as a nuclear medicine evaluation that measures radioisotope clearance by the kidney.

Further treatments based on disease biology

With rapid advances in neuroblastoma biology being made, future alternatives may include more biologic treatments. One agent in clinical trials is ^{131}I-MIBG, a compound that delivers radiation directly to catecholamine-secreting cells such as neuroblastoma. Studies have used ^{131}I-MIBG as part of the conditioning regimen before progenitor cell rescue in patients with neuroblastoma.[65] Tyrosine kinase inhibitors (eg, crizotinib, ceritinib), which target the anaplastic lymphoma kinase (ALK) receptor, have been studied in pediatric patients with *ALK* mutations and may benefit a small percentage of patients with neuroblastoma.[66–68]

Wilms Tumor

Description, Epidemiology, and Pathophysiology

Wilms tumor, also known as nephroblastoma, is a kidney tumor composed of various kidney cell types at different stages of maturation. Approximately 5% of all childhood cancers are Wilms tumor, representing about 650 new cases per year in the United States. Wilms tumor is the most common intra-abdominal tumor of childhood,[1,71] with a peak incidence at ages 3 to 4 years.[69]

The relationship of genetic factors to Wilms tumor is demonstrated by ~1.5% of patients with Wilms tumor who have family members with the disease, as well as around 10% of patients who have

congenital anomalies such as aniridia, hemihypertrophy, or genitourinary anomalies.[69] About one-third of Wilms tumor cases involve mutations in *WT1*, *CTNNB1*, or *WTX*.[4,70] Chromosomal aberrations at 11p13 and 11p15, known, respectively, as *WT1* and *WT2*, are associated with syndromic Wilms tumors commonly seen with WAGR syndrome (**W**ilms, **A**niridia, **G**enitourinary anomaly, mental **R**etardation; *WT1*) and Beckwith–Wiedemann (*WT2*) syndromes, respectively.[5,6,71] Patients with these related predisposition syndromes should be screened with ultrasonography every 3 months until at least age 8 years.[72] Other known syndromic causes may also be important, including a variety of overgrowth syndromes (Perlman, Simpson-Golabi-Behmel, CLOVES, etc), Bloom syndrome, and Li–Fraumeni syndrome.[3,69,73] Nonsyndromeic familial Wilms tumor is related to *WT4* (17q12-21) and *FWT2* (19q13.4), which have been identified more recently and about which less is known.[69]

Most patients with Wilms tumor may expect an excellent prognosis, with OS rates of about 90%.[35] However, prognosis varies with the presence of specific risk factors, such as the stage of disease at diagnosis, patient age (older age is less favorable), histopathology (anaplasia worse than favorable histology), and molecular features of the tumor.[69,74–77] Of all prognostic factors, 1q gain is the most powerful predictor of adverse/poor clinical outcomes.[76,77] Patients with adverse prognostic features typically receive augmented chemotherapy approaches (**Table 95-3**).

Table 95-3
Wilms Tumor Treatment Regimens by Stage and Histology

Stage I, Any Histology, and Stage II, Favorable Histology
Surgery followed by 18 weeks of vincristine and dactinomycin. Add abdominal radiation for either focal or diffuse anaplasia.[a]
Stage III or IV, Favorable Histology; Stages II, III, or IV Focal Anaplasia
Surgery followed by 24 weeks of vincristine, dactinomycin, and doxorubicin, with abdominal radiation.[b] Add pulmonary radiation if chest CT (computed

tomography) shows metastases unless there is complete resolution after chemotherapy.
Stages II through IV, Diffuse Anaplasia
Surgery followed by 24 weeks of vincristine, doxorubicin, etoposide, and cyclophosphamide with mesna, plus or minus dactinomycin and carboplatin, abdominal radiation. Stage IV: Add pulmonary radiation if chest CT (computed tomography) shows metastases unless there is complete resolution after chemotherapy.
Stage V
Biopsy followed by neoadjuvant vincristine, dactinomycin, and doxorubicin, then complete resection or debulking followed by more chemotherapy and, if a poor response, radiation therapy; more aggressive treatment if unfavorable histology.

[a]Stage I with tumor >550 g in a patient >24 months of age: surgery alone has been used investigationally with some success.

[b]Stage III or IV with favorable histology but loss of heterozygosity at 1p and 16q: higher risk, use vincristine, dactinomycin, doxorubicin, plus outpatient cyclophosphamide and etoposide.

CLINICAL PRESENTATION

Patients with Wilms tumor frequently present with an asymptomatic abdominal mass, although malaise and pain may be reported.[69] Hematuria and high renin hypertension each occur in ~25% of patients. Metastases, when present at diagnosis, most commonly involve the lungs (80%) or liver (15%).

DIAGNOSIS, STAGING, AND OVERVIEW OF TREATMENT

Diagnosis of Wilms tumor is based on biopsy and computed tomography (CT) of chest and abdomen to rule out metastatic disease. Fluorine F 18-fludeoxyglucose (^{18}F-FDG) positron emission tomography (PET)–CT (^{18}F-FDG PET-CT) may also be helpful in some patients.[78] Treatment in the United States is based mostly on disease stage after surgical resection or debulking and favorable

histology versus focal or diffuse anaplasia. Surgical resection is the primary treatment, followed by adjuvant chemotherapy (see Table 95-3). A simplified description of the staging is as follows: stage I (43% of patients) is limited to the kidney and can be completely removed surgically; stage II (20% of patients) is extended beyond the kidney but can be completely excised; stage III (21% of patients) is characterized by residual tumor confined to the abdomen; stage IV (11% of patients) is distant metastases; and stage V (5%) of patients is bilateral disease.[69] Metastases are present in only 15% of patients at diagnosis, and even these patients have relatively good prognoses. Notably, in Europe, the majority of treatments use neoadjuvant chemotherapy before surgery. The benefits and risks of each method have been discussed elsewhere.[79] COG studies suggest surgery followed by adjuvant chemotherapy, except in stage V (bilateral disease) where neoadjuvant chemotherapy is used in an attempt to preserve kidney function.[80] The late effects following treatment for Wilms tumor can be significant, including the development of subsequent or secondary malignant neoplasms, heart failure, pregnancy complications, and end-stage renal disease.[81–85] Long-term follow-up and monitoring of patients well into adulthood are critical.

CLINICAL PRESENTATION AND TREATMENT

CASE 95-2

Question 1: B.N. is a 34-month-old boy who is pale and irritable. He has had abdominal problems with decreased bowel movements and reduced oral intake for 2 weeks. He has played less than normal for the last 4 weeks. B.N.'s blood pressure has intermittently been as high as 146/87 mm Hg (normal, 90th percentile, 106/69 mm Hg). His laboratory results include the following:

Hgb, 7.9 g/dL (normal, 11.5–13.5 g/dL)
Erythrocyte sedimentation rate, 139 mm/hour (normal, <10 mm/hour)

B.N. has a history of hypospadias and left hydronephrosis. Scans show a right kidney mass extending through the capsule plus two distant metastases in the peritoneum. Chest radiography shows one nodule in the lung as well. Pathology from a biopsy sample shows favorable histology Wilms tumor.

What treatment should B.N. receive?

B.N. has stage IV disease with favorable histology, and the cells are negative for loss of heterozygosity at 1p and 16q. The expected treatment for him is 24 weeks of vincristine, dactinomycin, and doxorubicin, assuming findings at surgery are consistent with pretreatment scans. He will receive abdominal radiation; he would also receive pulmonary radiation unless the lung metastases completely disappear with chemotherapy. The series of five National Wilms Tumor studies have sought to progressively minimize toxicities from radiation and chemotherapy while maintaining an excellent cure rate. The fourth National Wilms Tumor Study Group (NWTS-4) study demonstrated that intermittent, higher doses of dactinomycin allowed higher dose intensity with less myelosuppression than lower doses given daily for 5 days. Using greater dose intensity and dose density, 6 months of therapy was shown to be as effective as 15 months of therapy given the traditional way.[86] Also, fewer clinic visits were made and estimated costs were reduced by 50%.[86,87] The NWTS-5 evaluated surgery followed by 18 to 24 weeks of chemotherapy. Chemotherapy was determined by the stage and histology findings (Table 95-3). Abdominal radiation therapy was added to chemotherapy for stage II disease with unfavorable histology (focal or diffuse anaplasia) or stages III or IV with any histology; pulmonary radiation was added for stage IV disease if the chest radiograph was positive for metastases. The latter part of the guideline is now determined by whether the pulmonary nodules clear with chemotherapy or not. For patients with stage V disease, or those with inoperable tumors, surgery could be delayed until neoadjuvant chemotherapy reduces the tumor size.

Dosing chemotherapy in infants and young children

CASE 95-2, QUESTION 2: Are there any special precautions for dosing chemotherapy in B.N.?

The NWTS-2 study noted an excessive number of toxic deaths in infants with good prognosis, and this resulted in a dosing change.[88] After chemotherapy doses were decreased by 50%, severe hematologic toxicity, toxic deaths, and pulmonary and hepatic complications were reduced.[89] Importantly, no decrease in therapeutic effect was noted. Reduction of chemotherapy doses in infants is a consideration for other pediatric cancers as well.[39–41] Reasons for increased toxicity in infants may include altered pharmacokinetics or organ sensitivity as well as the larger body surface area/kilogram relative to older children and adults.[88] In NWTS-5, dosages of chemotherapy agents for patients with Wilms tumor who are <66.13 pounds (30 kg) were converted from mg/m^2 to mg/kg. By assuming the average 1-m^2 child weighs 66.13 pounds (30 kg), the dose per square meter can be divided by 30 to arrive at a dose per kilogram, which can be used in dosing calculations. This adjustment lowers the dose by 20% to 50% in children who weigh <33.06 pounds (15 kg). In NWTS-5, infants younger than 12 months of age received doses that were further reduced by halving the milligram/kilogram dose. The COG has recently proposed an alternative approach using dose banding for infants and children with a body surface area (BSA) <0.6 m^2.[90] The proposed dose bands were developed to provide a more uniform drug exposure and safer dosing curve for infants and children up to about 36 months old during critical phases of ontogeny.

Interaction of chemotherapy with radiation

Case 95-2, Question 3: Are there any dosing precautions required because of potential interactions between B.N.'s treatments?

Another medication-related problem that may arise in B.N. is the interaction of dactinomycin and doxorubicin with radiation therapy.[91–95] Two effects have been reported. One is acute enhancement of radiation effects, and the other is recurrence (recall) of radiation effects up to several weeks later, especially to skin and mucous

membranes. Because B.N. is to receive abdominal and lung irradiation during his chemotherapy treatment, concurrent doses of dactinomycin and doxorubicin will need to be reduced by 50% and held if wet desquamation occurs at the radiation site. In many of the Ewing sarcoma and rhabdomyosarcoma protocols, dactinomycin or doxorubicin is stopped during concurrent radiation treatments.

Doxorubicin cardiotoxicity in pediatrics

Case 95-2, Question 4: When B.N. receives lung radiation for his metastases, how will it affect the doxorubicin he is scheduled to receive?

Although it is well known that mediastinal radiation can increase the risk of anthracycline-induced cardiac toxicity,[96] the only adjustment for B.N. would be a temporary reduction of doxorubicin doses (same reductions as described in Case 95-2, Question 3). The total doxorubicin dose should be limited to no more than 5 mg/kg (150 mg/m^2 in larger children). In earlier Wilms tumor studies, the risk of congestive heart failure was 4.4% at 20 years, or up to 17.4% in patients who relapsed and received more doxorubicin.[82] Thus, cardiovascular toxicity can develop as long as 20 years after therapy is completed, with an apparent decrease in left ventricular wall thickness and increased ventricular afterload, probably related to inadequate numbers of myocytes.[97] These reports emphasize the need to minimize chemotherapy in patients with good prognosis, as the Wilms tumor studies are doing. New recommendations include better standardization of cardiac monitoring and continuation of monitoring throughout life in survivors of childhood cancer who receive cardiotoxic agents.

Dactinomycin hepatotoxicity

Case 95-2, Question 5: B.N. is to receive vincristine 0.05 mg/kg weekly for 10 weeks; doxorubicin 1.5 mg/kg at weeks 3 and 9 and then decreased to doxorubicin 1 mg/kg at weeks 15 and 21; and dactinomycin 0.045 mg/kg at

weeks 0, 6, 12, 18, and 24. During the third week of treatment, his alanine aminotransferase (ALT) is elevated to 78 units/dL. Is this related to his drug therapy?

Early in the NWTS-4, an increased incidence (14.3%) of severe hepatotoxicity (elevation of alanine aminotransferase or ALT 10 times normal with or without ascites) was reported with the pulse-intensive dactinomycin doses (0.06 mg/kg/single dose) in patients receiving no abdominal radiation.[98] Subsequently, dactinomycin doses were reduced. Still, the incidence of hepatotoxicity in patients receiving the newer 0.045 mg/kg pulse doses (3.7%), as well as those receiving the standard 0.015 mg/kg/day for 5 days (2.8%), remained elevated relative to the NWTS-3 results (0.4%), which used the same 0.015 mg/kg/day for 5 days.[99] The reasons for the increased hepatotoxicity are not known. Liver function usually returns to baseline within 1 to 2 weeks after discontinuation of chemotherapy, although more severe problems with sinusoidal obstructive syndrome (hepatopathy, veno-occlusive disease) have also been reported. Chemotherapy may be restarted in some patients, although frequently at lower doses or without dactinomycin. B.N. should be monitored closely in case his liver enzymes continue to rise, especially because he will receive abdominal radiation treatments that may increase the risk of hepatic toxicity. If his ALT rises to two to five times normal, or his total bilirubin is 3 to 5 mg/dL, doses of all three of his drugs should be reduced by 50%, or according to protocol instructions. If his ALT or bilirubin rises above two to five times normal, the drugs should be withheld until laboratory values return to lower than the aforementioned ranges.

Osteosarcoma

Definition, Epidemiology, Pathophysiology, and Course of the Disease

Osteosarcoma is a malignant osteoid-producing bone tumor that occurs most commonly in adolescents or young adults in the second or third decade of life.[100,101] Osteosarcoma represents about 2% to

5% of all childhood malignancies, with around 450 new cases per year in children, adolescents, and young adults in the United States.[1] The most common manifestation at diagnosis is pain at the site, which can sometimes be present for several weeks to months. It occurs most frequently in the metaphyseal ends of the distal femur, proximal tibia, or proximal humerus, but can occur in the flat bones as well.

The age range and bones involved suggest a malignant response associated with normal childhood growth spurts.[103] Radiation from treatments or nuclear disasters has also been linked to osteosarcoma. Mutation of the retinoblastoma (*RB1*) gene increases the risk of osteosarcoma, and retinoblastoma survivors and carriers need to be monitored for osteosarcoma.[2,102] There are a number of other uncommon inherited conditions, such as Bloom syndrome, Diamond–Blackfan anemia, and Rothmund–Thomson syndrome, that are also associated with an increased risk of osteosarcoma.[3,73,103–105]

Typical staging systems are not used for osteosarcoma; however, presence of clinically detectable metastatic disease at diagnosis, resectability of the tumor, and tumor grade (high vs low) are important to outcomes. Low-grade tumors are not likely to metastasize and are not treated with chemotherapy in contrast to high-grade tumors. Clinically detectable metastases are present in 15% to 20% of patients, usually in the lungs but occasionally in the same or other bones. If surgery alone is used for treatment, 80% of patients will die within 5 years of recurrent metastatic disease, indicating the presence of subclinical micrometastases at the time of diagnosis.[100,101] The degree of tumor necrosis at surgical resection is an indicator of chemosensitivity of the tumor and risk of relapse. Greater than 90% necrosis at the time of surgery after six cycles of neoadjuvant chemotherapy is associated with a 70% to 80% chance of long-term survival for nonmetastatic disease, with survival dropping to around 50% for nonmetastatic disease with <90% necrosis.

CLINICAL PRESENTATION AND DIAGNOSIS

Because osteosarcoma usually presents close to a joint in long bones, it most commonly presents with pain or a limp. It is often thought to be an athletic injury at first. In some patients, a broken arm or leg will occur, bringing attention to the mass on radiographs. Diagnosis is based on pathology from a biopsy, which should be obtained by the surgeon performing the definitive surgery; therefore, the biopsy tract can be resected with the tumor.

TREATMENT OVERVIEW

Although surgery is the main treatment of the primary tumor, chemotherapy is used to prevent development of metastases in patients with high-grade osteosarcoma. Drugs frequently used for osteosarcoma include high-dose methotrexate, cisplatin, doxorubicin, and ifosfamide. Regimens have changed minimally in the last 25 years, with the current standard treatment in COG being cisplatin and doxorubicin alternating with two cycles of high-dose methotrexate, despite conflicting evidence for the inclusion of high-dose methotrexate.[106–108] Neoadjuvant chemotherapy is commonly given for six cycles and continued after surgery for 12 more cycles (for a total of 29 weeks). The tumor is relatively resistant to radiation therapy, which is usually reserved for cases in which local control cannot be achieved surgically.[100] Surgical procedures usually fit into two categories: limb preservation or salvages, or amputation with prosthetics. There are a number of versions of each type of surgery.[100,101] When chemotherapy is used with surgery in nonmetastatic patients, long-term (2–5 years) DFS is 50% to 85%.[100,101]

ROLE OF CHEMOTHERAPY IN TREATMENT

CASE 95-3

QUESTION 1: G.C. is an 18-year-old male with a 2- to 3-month history of left shoulder pain. A tumor is found on radiograph, and biopsy confirms a high-grade conventional osteosarcoma of the left proximal humerus. No apparent

metastases are found with CT and bone scans. Renal function, left ventricular ejection fraction, and hearing tests are all within normal limits. G.C. begins neoadjuvant chemotherapy consisting of high-dose methotrexate alternating with cisplatin and doxorubicin. Six cycles of this chemotherapy (cisplatin/doxorubicin twice and high-dose methotrexate four times) will be given before his surgery, after which he will receive two more cycles of cisplatin/doxorubicin, each followed by two cycles of methotrexate, then two more cycles of doxorubicin, each followed by two cycles of methotrexate.

What is the goal of chemotherapy? What is the role of presurgical (neoadjuvant) chemotherapy in G.C.?

GOAL OF CHEMOTHERAPY

Because G.C.'s osteosarcoma is in his proximal humerus, the surgeon can remove the primary tumor using one of the various operations described in the literature.[100,101] Limb salvages typically work well in the upper extremities, with fewer complications than when they are used for lower extremities. Because patients with osteosarcoma usually die from metastases, the goal of the chemotherapy is to eradicate micrometastases, which are present more than 80% of the time, as discussed in the previous section. Neoadjuvant chemotherapy of osteosarcoma was developed to treat micrometastases while waiting for limb salvage surgeries to be arranged, performed, and healed. Neoadjuvant therapy may improve limb-sparing surgery by shrinking the tumor; it also allows histologic grading of the response to initial chemotherapy at surgery, a prognostic factor for risk of relapse (see Case 95-3, Question 2). However, no convincing evidence to date indicates that DFS is better for patients who receive neoadjuvant chemotherapy relative to those who receive their chemotherapy as adjuvant therapy.[100] In G.C., a titanium bone implant was placed where the diseased humerus was removed. The ease of doing this surgery may have been enhanced by neoadjuvant chemotherapy-induced shrinkage of the tumor.

PROGNOSTIC FACTORS

Case 95-3, Question 2: At surgery, G.C.'s tumor shows excellent histologic response, shown by 99% necrosis of the tumor sample. At diagnosis, his LDH

was 220 units/L. How do these prognostic factors affect the choice of therapy in osteosarcoma?

Conventional staging systems do not correlate well with prognosis for most bone cancers. Clinically apparent metastases or a location that does not allow complete surgical removal of the primary tumor are associated with a poor prognosis.[100,101] Newer surgical techniques and treatments have improved the prognosis with 20% to 30% of metastatic patients cured using neoadjuvant chemotherapy and surgery. Other potential prognostic factors have been identified; however, few of these factors have been used to stratify patients to different treatment regimens. G.C. has a minimally elevated LDH consistent with a relatively small tumor mass, although this is not used to stratify for treatment. The percentage necrosis of the tumor at surgery correlates with risk of recurrence. In current studies, patients with >90% tumor necrosis after six cycles of neoadjuvant chemotherapy are considered good risk and are treated with standard chemotherapy such as G.C. is receiving. Patients whose tumors have less necrosis at surgery are considered to be standard risk, and they have a higher risk of treatment failure. No treatment modifications to date have demonstrated better outcomes for these patients than the good risk protocol described above.

DELAYED CLEARANCE AFTER HIGH-DOSE METHOTREXATE

Case 95-3, Question 3: After reconstructive surgery using a titanium implant, G.C. restarts his chemotherapy. During his fourth cycle of chemotherapy, after high-dose methotrexate is given, G.C.'s peak methotrexate concentration is 1300 micromolar (μM) and the 72-hour concentration is 0.22 μM (normal, ≤0.1 μM at 72 hours). Urine specific gravity has remained at 1.010 or less, urine pH between 7 and 8, and urine output has been >2 to 3 mL/kg/hour, which, according to guidelines, suggest a reduced risk of methotrexate-induced nephrotoxicity. His creatinine has increased from 0.9 to 1.1 mg/dL (eGFR of 106 mL/minute/1.73 m^2); he does not have any signs or symptoms of methotrexate toxicity in spite of his delayed clearance. Leucovorin rescue (15 mg IV every 6 hours beginning at hour 24) is continued. What potential problems could be causing his retention of methotrexate?

Accumulations of protein-containing fluids (called third spaces), such as pleural effusion and ascites, or GI obstruction, may retain methotrexate and slow the terminal excretion.[109–111] Slow excretion of methotrexate allows more proliferating cells to be exposed to methotrexate during the S phase of the cell cycle, increasing the cytotoxicity and resulting in more mucositis and myelosuppression. Some host-related factors, such as biologic sex (males more than females), race/ethnicity, and germline genomics (eg, single-nucleotide polymorphisms) may affect methotrexate pharmacokinetics and pharmacodynamics.[112–116] Many drugs interact with methotrexate, which can also slow its excretion.[113,117,118] Cisplatin may reduce the excretion of methotrexate because of the risk of platinum-related nephrotoxicity, especially at cumulative cisplatin doses >300 mg/m^2. G.C. has received four doses of 120 mg/m^2 (480 mg/m^2 total dose) of cisplatin, which may have contributed to the reduced methotrexate excretion. He has not received other nephrotoxic agents concomitantly, such as aminoglycosides or amphotericin B. Weak organic acids, such as salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), penicillins, or trimethoprim–sulfamethoxazole (TMP–SMX), can compete with methotrexate for renal tubular secretion via the organic anion transport system.[119] A single-center study suggested that prophylactic TMP–SMX may not pose a serious drug interaction risk with high-dose methotrexate, although this practice is not yet widely adopted.[120] Lastly, proton-pump inhibitors may directly inhibit renal transporter proteins and have been reported to delay methotrexate excretion.[118,121,122]

Although G.C.'s serum creatinine appears to be the same that it was at diagnosis (1.1 mg/dL), serum creatinine is not always a good indicator of renal function, so it is possible that G.C. has had some renal damage that is not apparent from his serum creatinine concentrations.[62] A measured creatinine clearance was 176 mL/minute/1.73 m^2 at diagnosis, and a repeat at this point is 106 mL/minute/1.73 m^2. Measurements and estimations of glomerular filtration are not well correlated in children with cancer.[62,64,123] Although the reduced renal clearance may be contributing to a slight

delay in clearance, it is not clear if this is because of normal variation or a specific pathology; future courses of methotrexate need close monitoring.

LEUCOVORIN RESCUE

CASE 95-3, QUESTION 4: How long should leucovorin be administered to G.C.?

Leucovorin is a tetrahydrofolate that bypasses methotrexate's block of dihydrofolate reductase and reduces the toxicities of high-dose methotrexate. It therefore can be used as a form of methotrexate rescue. Cytotoxic effects of methotrexate depend on concentration and duration of exposure.[124] Many high-dose methotrexate protocols continue leucovorin rescue until serum methotrexate concentrations are <0.1 μM, which would be expected to occur ~72 hours after a 12 g/m^2 dose infused over 4 hours. Because G.C. has delayed methotrexate clearance with persistence of methotrexate levels still above 0.1 μM at 72 hours, prevention of GI and bone marrow cytotoxicity may require continuation of leucovorin rescue until methotrexate concentrations are <0.05 μM.[117] For G.C., methotrexate concentrations did not fall below 0.1 μM until 108 hours after his dose; thus, leucovorin was continued 24 hours past that time to ensure presence until methotrexate fell below 0.05 μM. Other considerations may also be important in patients receiving leucovorin rescue. Because of the competitive nature of leucovorin rescue, higher leucovorin doses may be needed for patients with excessively high methotrexate concentrations.

Methotrexate concentrations above a certain threshold or for a certain duration of time can place patients at high risk for methotrexate toxicity.[125] Methotrexate doses (12 g/m^2) infused over 4 hours are designed to produce peak methotrexate concentrations in the blood of 1000 μM, followed by <10 μM at 24 hours, 1 μM at 48 hours, and 0.1 μM at 72 hours. Higher concentrations may result in greater toxicity and additional leucovorin doses may be necessary.[117,125] If G.C.'s methotrexate concentrations had remained

more than 1 μM 48 hours after the beginning of the infusion, it is recommended to increase the leucovorin dose to 15 mg/m^2 every 3 hours until methotrexate concentrations fall below 0.05 μM.[117,126] If concentrations exceed 5 μM 48 hours or more after the methotrexate dose, higher doses of leucovorin are recommended (150 mg/m^2 every 3 hours). Oral leucovorin administration should not be used when the patient has emesis or requires large oral doses (about 40 mg), which are often poorly absorbed.[126] If a patient on high-dose methotrexate experiences renal failure and has elevated concentrations of methotrexate, glucarpidase may be used in addition to the leucovorin. Glucarpidase hydrolyzes methotrexate into inactive compounds and is very effective at quickly lowering methotrexate concentrations; however, it generally needs to be administered within the first 96 hours after the methotrexate dose. In spite of rapid reduction of methotrexate concentrations, it is not clear the extent to which it lowers morbidity or mortality from the high levels and delayed clearance.[117,126]

Rhabdomyosarcoma

Description, Epidemiology, and Pathophysiology

Rhabdomyosarcoma is a soft tissue tumor of mesenchymal origin.[127] It is the most common soft tissue sarcoma of childhood, occurring in about 3% of all children and adolescents with cancer.[1] The annual incidence in the United States is about 4.5 cases per 1 million children, representing about 350 new cases per year.[127] About half of all cases occur in the first decade of life.[128]

The two most common histologic types of rhabdomyosarcoma in children are embryonal (57% of cases) and alveolar.[127] Embryonal rhabdomyosarcoma cells resemble striated muscle and occur most frequently in young children with involvement in the head and neck or genitourinary tract. Alveolar rhabdomyosarcoma cells resemble lung parenchymal cells and occur more frequently in older children or adolescents with involvement of the trunk or extremities. Generally, patients with alveolar rhabdomyosarcoma have a poorer

prognosis than patients with the embryonal type. Recent studies suggest that alveolar-appearing rhabdomyosarcoma cells without the *PAX3*/*PAX7-FOXO1* fusion gene are molecularly and clinically identical to embryonal and may be treated as such, although this is not current practice in protocols.[129,130]

Most patients with rhabdomyosarcoma have no known risk factor or genetic predisposition to developing the tumor. However, some genetic factors may be associated with rhabdomyosarcoma, including Li–Fraumeni syndrome (germline *TP53* mutations), *DICER1* syndrome, neurofibromatosis type 1 (*NF1*), and Costello syndrome (*HRAS* mutations).[131–136]

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical presentation of rhabdomyosarcoma varies with its location (head and neck, genitourinary, parameningeal, extremity, orbit, as noted above). Diagnosis involves a biopsy of the tumor, which can be examined for appearance under an electron microscope, and a number of tests are run to identify molecular markers to differentiate it from other small, round cell tumors.[127] Patients with localized disease at presentation have a high chance for cure using conventional, multimodal therapies.[137,138] Conversely, patients with unresectable or metastatic disease have a higher risk for relapse and poor prognosis.[139] Other poor prognostic features include age (<1 year or older than 9 years at diagnosis), tumor size >5 cm, alveolar histology, lymph node involvement at diagnosis, site of primary tumor (biliary, extremities, trunk, and abdomen being some of the least favorable), and certain molecular features.[127]

TREATMENT OVERVIEW

Treatment combines surgery, radiation, and chemotherapy. Complete surgical removal is often difficult, given the locations and infiltrative characteristics of rhabdomyosarcoma. Because good local control improves the prognosis,[127] radiation is generally administered after the surgery. Combination chemotherapy is necessary because the 5-year survival with local control alone is only 10% to 30%. More

than 90% of patients at low risk (those in subgroup A with localized, embryonal tumors in favorable sites) may expect long-term survival with the two-drug regimen of vincristine and dactinomycin (VA), with or without radiation based on the extent of disease.[140] Patients with more advanced disease will require the addition of cyclophosphamide. The vincristine, dactinomycin, and cyclophosphamide (VAC) regimen has been used extensively to treat rhabdomyosarcoma.[127] Unfortunately, the dose of cyclophosphamide required to achieve long-term cure can also induce sterility. Attempts to limit both radiation exposure and the cumulative cyclophosphamide dose have not always been successful, with some patients experiencing suboptimal survival with reduced intensity regimens.[141,142] Other agents producing responses include combinations of vincristine, doxorubicin, and cyclophosphamide; ifosfamide and etoposide; and vincristine and irinotecan.[127] Using the combination of VAC with local control of surgery or radiation in the fourth Intergroup Rhabdomyosarcoma Study (IRS) resulted in a 76% failure-free survival for patients with nonmetastatic disease.[138]

CLINICAL PRESENTATION, PROGNOSTIC FACTORS, AND TREATMENT

CASE 95-4

QUESTION 1: F.J. is a 2-year-old female with a rapidly enlarging mass on the lateral head of the gastrocnemius muscle in the right calf. Bone marrow and scans are negative for metastatic disease. The diagnosis is embryonal rhabdomyosarcoma, stage III (unfavorable site and >5 cm mass). Initial expectations were that gross residual tumor would remain after the surgery, consistent with clinical group III. Chemotherapy consists of 3-week cycles of vincristine 0.05 mg/kg (days 1, 8, and 15 of some cycles but day 1 only of some cycles); dactinomycin 0.045 mg/kg on day 1 of each cycle; and cyclophosphamide 73 mg/kg on day 1 of each cycle with mesna to reduce the risk of hemorrhagic cystitis. Because of reports of hepatotoxicity during a prior study, especially in patients younger than age 3 years, the protocol recommends all three drugs be dosed in milligram/kilogram for children younger than age 3 years. Prophylactic TMP–SMX is begun at 150 mg/m^2/day (TMP)

divided twice daily for three consecutive days/week. After each course of chemotherapy, F.J. is to receive filgrastim 5 μg/kg/day subcutaneously for 14 days or until the absolute neutrophil count (ANC) is >750 cells/μL.

What factors in F.J. are associated with a good prognosis? What chemotherapy treatment would be most appropriate for F.J.?

The embryonal histopathologic classification has a better prognosis than the alveolar one, although evidence indicates that the location of the primary tumor is more important than the histology.[127] The primary site affects resectability, route of spread, and how early the diagnosis is made. Additionally, age between 1 and 9 years is associated with a better prognosis. The IRS have used a clinical grouping system (groups I–IV), which is based on spread of the disease and extent of resection. This system has been useful because of its correlation with prognosis where complete surgical removal and lack of metastases both correlate with good prognosis.[127] The fourth and fifth IRS studies compared the clinical grouping system with a TNM (tumor, lymph node, metastasis) staging system similar to that used in adult cancers. Although the two systems may result in different disease stages for a specific patient, both are considered valuable and current protocols use both systems.

In rhabdomyosarcoma, the tumor site is one important part of the T rating in the staging system. F.J.'s tumor involves an unfavorable site (the calf) and is >5 cm, making it stage III. Although her tumor was expected to be clinical group III, after a good response to neoadjuvant chemotherapy, a complete resection was performed, making it clinical group I. This suggests that she has an 80% to 90% chance of 3-year survival based on the IRS-II, IRS-III, and IRS-IV results.[127,137,138,143] The IRS-V classified patients as having low-risk, intermediate-risk, or high-risk disease. Patients at low risk include those with embryonal rhabdomyosarcoma at favorable sites, or at unfavorable sites with no more than microscopic residual tumor.[127] Patients at intermediate risk have the embryonal subtype with gross residual tumor or the alveolar subtype without metastatic disease.

Patients at high risk include those with metastatic alveolar or embryonal disease.

Chemotherapy for many patients at low risk is limited to vincristine and dactinomycin.[127] Most at intermediate risk are treated with VAC. Patients at high risk have not responded well in the past and are candidates for trials with newer drugs added to the VAC. A recent study added courses of vincristine and irinotecan, ifosfamide and etoposide and vincristine, doxorubicin, and cyclophosphamide (COG ARST0431), and 3-year event-free survival appears good compared to historical data for patients with 0 to 1 higher-risk features.[144] F.J. would be in the low-risk group; however, her large initial tumor justifies adding cyclophosphamide to the vincristine and dactinomycin as in the intermediate-risk regimen. Because radiation to her leg would stop bone growth and her surgical margins were tumor free, no radiation is being administered.

TRIMETHOPRIM–SULFAMETHOXAZOLE PROPHYLAXIS AND FILGRASTIM FOR MYELOSUPPRESSION

Case 95-4, Question 2: What are the reasons for treating F.J. with TMP–SMX and filgrastim?

F.J.'s VAC regimen was associated with a high incidence of neutropenic fevers even during the pilot studies. Because of the frequency of severe myelosuppression, TMP–SMX is used until 6 months after chemotherapy for prophylaxis against *Pneumocystis jirovecii*, an opportunistic pathogen. Filgrastim is used to minimize neutropenia so that the chemotherapy dose intensity can be maintained.

RENAL FANCONI SYNDROME WITH IFOSFAMIDE

Case 95-4, Question 3: F.J.'s mother read on the Internet about a patient with rhabdomyosarcoma who had received vincristine, ifosfamide, and etoposide and was cured. She wants to know why that regimen is not being used for her daughter. What would be the rationale for F.J.'s regimen?

The IRS-IV results for local or regional disease (intermediate risk) demonstrated no advantages of vincristine, ifosfamide, and etoposide or vincristine, dactinomycin, and ifosfamide over the standard VAC treatment.[138] Additionally, the ifosfamide-containing regimens caused more toxicity. Ifosfamide has been associated with renal Fanconi syndrome, a proximal tubular defect that is characterized by wasting of electrolytes, glucose, and amino acids, as well as renal tubular acidosis and, in a minority of cases, an increased serum creatinine. Data suggest that the risk of Fanconi syndrome is increased in children that are younger than 3 years of age; have received total ifosfamide doses >72 to 100 g/m^2; have hydronephrosis, a single kidney, or an elevated serum creatinine; or have received previous platinum therapy.[145–147] During each course of her chemotherapy, F.J. exhibits ketonuria; however, this is not a toxicity of her chemotherapy. Ketonuria is caused by her mesna therapy, which has been reported to routinely cause false-positive ketone tests.[148]

ACUTE LYMPHOBLASTIC LEUKEMIA OF CHILDHOOD

Acute leukemia is a malignancy of blood-forming cells involving the lymphoid and myeloid cell lines. The two most common types of childhood leukemia are acute lymphoblastic leukemia (ALL) and acute myelogenous leukemia (AML), with the former accounting for 75% of cases and the latter for ~15%. ALL is the most common childhood cancer, with ~3000 new cases of childhood ALL diagnosed each year in the United States.[149] A distinct peak incidence occurs at ages 2 to 3 years (>80 cases/million) and then decreases substantially for 8- to 10-year-olds (20 cases/million). A higher incidence of ALL is seen in White children than in African American children. This racial difference is most apparent in the 2- to

3-year-old age group, with a nearly threefold greater incidence rate for White children.[149,150] Before the early 1970s, ALL was a fatal illness with most children succumbing to their disease within 2 to 3 months after diagnosis. Today, around 90% of children achieve prolonged survival with antileukemic therapy.[149,150] New innovations in therapy for ALL continue to improve survival while decreasing the long-term morbidity associated with treatment.[27]

Epidemiology and Etiology

The etiology of ALL is largely unknown with only a small percentage of cases being associated with environmental factors such as chemical or radiation exposure.[27,151] Genetic factors may also increase the risk of ALL, most notably Trisomy 21 or Down syndrome. Children with Down syndrome have a 20-times higher incidence of developing ALL.[152] Germline mutations in ETV6 and PAX5 have been found in rare cases of familial ALL.[27]

Pathophysiology

The development of ALL involves replacement of normal bone marrow elements with a clone of immature lymphoid cells. The essential lesion in ALL is stabilization of a malignant cell in the lymphocyte differentiation process. Many factors are involved in the control of normal cellular proliferation. Leukemia may represent a disruption in one or more of the normal relationships within the cell proliferation pathway, such as an abnormal response to lymphoid cell-growth factors.[27,153]

With the availability of classification systems of lymphoblasts based on morphology, immunology, and cytogenetics, it has become clear that ALL is a heterogeneous disease. This is especially true regarding cytogenetic abnormalities. The immunologic heterogeneity results from leukemic transformation at various stages of lymphocyte differentiation. Molecular classification involving gene expression profiling allows for further classification of ALL cytogenetic subtypes,

helping predict response to therapy.[154] As discussed later in this section, these classifications have important prognostic value.

Clinical Presentation

The signs and symptoms of ALL are nonspecific and many are shared with other childhood diseases such as juvenile idiopathic arthritis (JIA). These signs and symptoms reflect uncontrolled growth and differentiation of the leukemic clone and the resulting deficiency in normal bone marrow elements, namely neutrophils, red blood cells (RBCs), and platelets. Frequent clinical findings include fever (53%), bleeding (38%), and bone pain (43%).[153,155] Bone pain is believed to be the result of hypercellular bone marrow and infiltration of leukemic lymphoblasts into pain-sensitive structures such as the periosteum. Although bone pain may be severe, it quickly resolves once chemotherapy is initiated. On physical examination, many patients have pallor (54%), bruising (52%), splenomegaly (61%), or hepatomegaly (64%).[155]

At diagnosis, at least 59% of patients have a normal or low WBC count; the remainder have elevated counts.[27,153] The WBC differential typically shows a low percentage of neutrophils and bands with a marked lymphocytosis. Lymphoblasts may be present in the peripheral blood even with a low WBC count, but they are more likely when the WBC count is elevated.[156] A normochromic, normocytic anemia, along with thrombocytopenia, is present in most patients.[27,153]

Diagnosis

A bone marrow aspirate and biopsy are usually necessary to confirm the diagnosis of ALL. In patients with elevated WBC counts, the diagnosis can be confirmed by studies of lymphoblasts in the peripheral blood. The diagnosis of ALL is made when at least 25% of lymphoid cells in the bone marrow are blasts.[153] Most patients with ALL have far greater than 25% blasts and many have complete

replacement of bone marrow with lymphoblasts. Once a child is diagnosed with ALL, it is important to determine the disease characteristics that influence treatment decisions and prognosis.[153,157]

Prognostic Variables

Significant research has focused on risk stratification of pediatric patients with ALL to allow for risk-adapted treatment regimens. Clinical findings present at diagnosis, immunologic and genetic properties of leukemic cells, and evaluation of early response to treatment can predict a specific patient's risk of relapse. Children with ALL are classified by their risk of relapse into one of the following categories: standard, high, or very high risk.[27]

CLINICAL VARIABLES

Childhood patients with ALL are assigned an initial risk group based on age and WBC count at presentation. These variables are referred to at the National Cancer Institute (NCI) criteria.[156] More recently, the presence of central nervous system (CNS) leukemia and/or testicular involvement has been added as a high-risk feature.[158]

Patients younger than 1 year or older than 9.99 years at diagnosis tend to have worse prognoses.[156] Older patients are more likely to have unfavorable immunophenotypes and genetic features such as T-cell ALL or BCR-ABL fusion, while the favorable features ETV6-RUNX1 and hyperdiploidy are more common in children ages 1 to 9.99 years.[159]

Age is particularly important for infants in which survival is exceedingly poor compared with other age groups and is frequently associated with the unfavorable KMT2A (formerly MLL) gene rearrangement. For infants, even with intensified chemotherapy regimens, long-term, DFS is <50%.[160] Approaches to improve outcomes in this age group have included stem cell transplant and targeted therapy with clinical research ongoing.

The initial WBC count is an important predictor of outcome in childhood ALL and retains its significance after adjustment for other important prognostic criteria.[153] Children with the highest WBC counts at presentation have the shortest duration of complete remissions. Although exactly where the demarcation line is for predicting a good or a poor prognosis is unknown, an initial WBC count >50,000 cells/μL is generally associated with a poor prognosis.[153,156]

IMMUNOLOGIC VARIABLES

ALL is classified into different immunologic subsets based on cell-surface markers or antigens present on the leukemic lymphoblasts at diagnosis. These can be categorized as cells of B-cell and T-cell origin. The B-cell lineage is further classified into subtypes reflecting the various stages of differentiation at which leukemia may develop. Approximately 15% to 20% of children with ALL have leukemia with a T-cell lineage, whereas more than 80% have leukemia of pre–B-cell or early pre–B-cell origin.[27,159] Leukemia with a mature B-cell origin is referred to as Burkitt leukemia and comprises 1% to 2% of leukemia in children.[159,161]

Burkitt leukemia has traditionally been associated with a poor prognosis, but prognosis has improved greatly with the advent of short-term, very intensive chemotherapy.[27,153] Although differences in outcome have been noted among the B-cell subtypes, when other prognostic factors are considered and when effective therapy is used, these differences may no longer be evident. At present, immunologic features that differentiate B-cell precursor, T-cell, and mature B-cell ALL are clinically important because different types of chemotherapeutic strategies are used for these three immunophenotypes.

Patients with T-cell ALL have several distinguishing features, including a greater likelihood of being male, Black, older, high initial WBC counts, and the presence of a mediastinal mass or initial leukemic involvement of the CNS.[27] Patients with T-cell ALL historically have had a decreased survival, although more intensive

treatment is improving their outcomes.[27] Studies with more intensified therapy also demonstrate no difference in relapse between T-cell and B-cell lineage ALL, although patients with T-cell ALL tend to relapse much earlier.[162–164]

CYTOGENETIC VARIABLES

Advances in chromosomal analysis have improved the understanding of ALL biology. Abnormalities in either chromosome number (ploidy) or structure of the leukemic clone have been found in 60% to 75% of ALL cases. Many of these abnormalities appear to have prognostic importance.[27] Ploidy is represented by the DNA index. A value of 1.0 indicates a normal number of chromosomes, and a value >1.0 indicates an increased number of chromosomes by a multiplication factor of the normal chromosome number. Children with leukemia blasts containing more than 50 chromosomes (DNA index ≥1.16, hyperdiploid) have an increased probability of continuous complete remission versus patients with leukemia blasts containing a diploid chromosome complement or with a DNA index <1.16.[159] ALL cells with a higher DNA index are more sensitive to antimetabolites (eg, mercaptopurine) and asparaginase.[165] In contrast, patients with hypodiploidy (<44 chromosomes and, in particular, those with 24–28 chromosomes) have significantly worse outcomes with an expected 40% EFS.[159] Hyperdiploidy is seen in 30% of cases of childhood ALL, whereas hypodiploid is observed in <5% of patients.[159,161]

Translocations are the most common structural abnormalities occurring in leukemic cells, providing insight into expected treatment outcomes.[151,161] Certain translocations are associated with treatment failure and relapse.[27] The translocation commonly associated with infants is called KMT2A located at 11q23 (also called MLL) and is associated with poor outcomes.[27,159] Commonly known as the Philadelphia chromosome, the *BCR-ABL* fusion transcript t(9;22)(q34.1;q11.2) occurs in 3% to 5% of childhood ALL cases.[27] Historically, children with the Philadelphia chromosome were considered at very high risk of relapse; however, the addition of

tyrosine kinase inhibitors such as imatinib and dasatinib to traditional chemotherapy has dramatically improved survival in this group of patients.[166,167]

An emerging group of translocations identified as Philadelphia chromosome-like involves various activating mutations involving ABL-class kinases other than BCR-ABL1 or the JAK-STAT pathway. These translocations also are recognized to have a higher incidence of relapse, although ongoing research is exploring targeted therapies such as ruxolitinib and dasatinib to improve outcomes.[159,161] Identification of other unfavorable translocations such as iAMP21, TCF3-PBX1, and IKZF1 have allowed for augmented treatment and improved outcomes in select patients as well.

One of the most common fusions found in 25% of patients with ALL is ETV6-RUNX1 (formerly TEL-AML1) and is associated with cure in over 90% of patients.[27,159] Other favorable changes include trisomies of certain chromosomes, specifically chromosomes 4, 10, and 17.[168]

MINIMAL RESIDUAL DISEASE

One of the most powerful ways to affect patient outcome is to measure response to current therapy and make adjustments when a patient is not responding as expected. Historically, bone marrow and peripheral blood evaluations were taken at various time points during treatment to gauge an early response to leukemia therapy. A major breakthrough in evaluating response to ALL therapy involves measurement of minimal residual disease (MRD) using flow cytometry and polymerase chain reaction (PCR) to detect a leukemia burden in the bone marrow of as low as 1 cell per 100,000 normal cells.[169–171]

A variety of lymphoblast characteristics, including gene fusion transcripts, immunophenotype, and antigen receptor gene rearrangements, may be relied on for MRD detection in children with ALL. Although specific fusion transcripts can be relied on as PCR targets in only one-third of childhood ALL cases, clonal antigen receptor gene rearrangements occur in virtually all cases.[169–171] It is

now established that the presence of MRD is an important prognostic factor, regardless of the patient's initial WBC count or age at presentation. A large study of the prognostic value of MRD for day-7 blood samples and for bone marrow samples at both the end of the induction and consolidation phases demonstrated that MRD at the end of the induction phase was the most important predictor of prognosis when compared to other laboratory and clinical factors.[170] Data from this study for end of induction MRD demonstrated major differences in 5-year event-free survival as follows: 88% for MRD-negative, 74% for MRD of 0.01% to 0.1%, 63% for MRD of 0.1% to 1%, and <40% for MRD >1%. Patients with MRD detectible at the end of consolidation had a poor prognosis with only 39% EFS. Monitoring of MRD is now established in the management of childhood ALL and is being used to risk-stratify treatment in current frontline leukemia studies.[27,170]

Overview of Treatment

The treatment for pediatric ALL is organized into different phases of chemotherapy. Treatment begins with induction therapy, which typically includes three or four systemic agents in addition to CNS preventive therapy. The intensity of induction therapy is based on the patient's NCI risk group. Induction therapy is designed to induce a complete remission and typically lasts 28 days. After induction therapy, the next phase of therapy can be defined as postinduction therapy and consists of several different cycles of chemotherapy referred to by such terms as consolidation, delayed intensification, and interim maintenance. This phase of intensive chemotherapy usually uses combination approaches that are somewhat different than induction therapy and that are designed to kill leukemia cells in the cell cycle that were not destroyed by induction therapy. Postinduction therapy is continuing to undergo substantial revision as studies determine which therapy components are optimal for various patients. The duration and intensity of this phase is tailored based on certain prognostic features of leukemia as outlined above.

The third phase of therapy is termed the maintenance phase, and it represents the longest phase of chemotherapy for these patients, taking ~2 years to complete. Maintenance therapy is typically less intensive than the previous phases and consists mostly of continuous oral chemotherapy with infrequent intravenous and CNS therapy. In general, treatment intensity diminishes from the induction/consolidation phase to the maintenance phase.

REMISSION INDUCTION THERAPY

Goal of induction

CASE 95-5

QUESTION 1: J.B. is a 4-year-old male presenting with a 2-week history of an upper respiratory tract infection and a 1-week history of otitis media. His symptoms have worsened, and he now presents with a nosebleed and fatigue. Physical examination reveals appreciable pallor and hepatosplenomegaly. A complete blood count (CBC) with differential reveals a normochromic, normocytic anemia with the following:

Hematocrit (Hct), 15.7%
Hgb, 5.7 g/dL
WBC count, 4300 cells/μL
Platelet count, 13,000 cells/μL

A differential on the WBC count reveals 82% lymphocytes (normal, 30%–40%), 7% neutrophils (normal, 50%–60%), and 11% lymphoblasts (normal, 0%). Based on these findings, a bone marrow biopsy is performed that reveals 95% lymphoblasts. A diagnosis of ALL is made. The immunologic class is early pre–B cell based on CD10 and CD19 positivity. Radiography of the chest does not reveal a mediastinal mass, and a lumbar puncture shows that there are no leukemic lymphoblasts in the cerebrospinal fluid. J.B. is hydrated, alkalinized, and treated with oral allopurinol 200 mg/m^2/day, with a plan to institute induction therapy the next day. Within a few days, J.B. will be treated with several drugs for his leukemia.

What is the goal of the induction therapy that J.B. will receive?

The goal of induction therapy is complete remission (ie, the inability to detect leukemic cells in the peripheral blood or the bone marrow by morphologic microscopic evaluation). J.B.'s peripheral blood values must be within the normal range, and the bone marrow

morphology must reveal <5% lymphoblasts with a goal MRD <0.01% by the end of induction therapy (ie, day 29). This definition also assumes the absence of lymphoblasts in the cerebrospinal fluid (CSF). Although these findings indicate an adequate response to chemotherapy, they do not indicate a cure. Most patients have a total of 10^{12} cells at diagnosis and successful induction regimens reduce this cell load by 99% to 10^{9}.[172] Therefore, continuation of therapy will be required for J.B. to further reduce the leukemic cell population and to increase his chances of long-term survival. Without continuation of therapy, the majority of patients with ALL will relapse within a few months.[27,158]

Induction combination chemotherapy

CASE 95-5, QUESTION 2: Which agents should be used to achieve complete remission?

The agents most commonly used in remission induction therapy are vincristine, prednisone or dexamethasone, pegaspargase, and daunorubicin (**Table 95-4**).[173,174] Dexamethasone has supplanted prednisone as the corticosteroid used during induction therapy in many cases. This is based on earlier work showing that dexamethasone has greater CSF penetration.[175] In patients with standard-risk ALL, a randomized comparison of dexamethasone to prednisone for induction therapy showed a lower CNS relapse rate in the dexamethasone group.[173,175] However, the use of a 28-day course of dexamethasone during induction for patients with high-risk ALL was also associated with an increased risk of infectious complications and avascular necrosis of the joints in adolescent patients.[176] This has led to the removal or alteration of dexamethasone during induction therapy in high-risk patients. It is plausible that the combination of dexamethasone and the intensive high-risk ALL induction chemotherapy increases the risk of infection because it causes more myelosuppression.

Table 95-4

Systemic Induction Regimens for Childhood Acute Lymphocytic Leukemia

Agent	Route	Dose/Schedule
Three-Drug Induction Regimen		
Prednisone	PO	60 mg/m^2/day × 28 days
Or		
Dexamethasone	PO	6 mg/m^2/day × 14[a] or 28 days
With		
Vincristine	IV	1.5 mg/m^2/week (max 2 mg) × 4 doses
And		
Pegaspargase	IM or IV	2500 units/m^2 × 1 dose
If Four-Drug Induction		
Daunorubicin	IV	25 mg/m^2/week × 4 doses

IM, intramuscularly; IV, intravenously; PO, orally.

[a]Dexamethasone duration may be shortened from 28 to 14 days when given as part of a four-drug induction regimen including daunorubicin.

Sources: Maloney KW, Devidas M, Wang C, et al. Outcome in children with standard-risk B-cell acute lymphoblastic leukemia: results of Children's Oncology Group trial AALL0331. *J Clin Oncol.* 2020;38:602–612; Bassen R, Holezer D. Modern therapy of acute lymphoblastic leukemia. *J Clin Oncol.* 2011;29:532–543.

No chemotherapy drug meets the criteria of an ideal agent (ie, toxic to leukemic cells only and active in all phases of the cell cycle). Corticosteroids, vincristine, and asparaginase come closest to this ideal in terms of activity, primarily against lymphoblastic leukemia, because these agents are selectively toxic to the leukemia cells, whereas sparing normal bone marrow elements. To improve the success in attaining complete remission, additional agents have been added to vincristine, corticosteroid, and asparaginase (see Table 95-4). The most frequently used additional agent is an anthracycline, such as daunorubicin or doxorubicin. Use of at least a three-drug induction regimen is the current standard of care for children at low or intermediate risk of relapse and results in

improvements in both remission rate and duration versus less intensive therapy.[173] Currently, a four-drug regimen, or an even more intensive induction regimen consisting of more than four drugs, and often for a duration of more than 4 weeks, is used for children at high risk of relapse and adult patients with ALL.[177–179]

Intensive induction treatment has benefits for the majority of children with ALL. This treatment strategy supports the hypothesis of Goldie and Coldman[180] that intensification of early treatment may decrease the chance that drug resistance will develop. This may therefore increase the proportion of long-term relapse-free survivors. Induction therapy is determined based on clinical findings, such as age at diagnosis and initial WBC count. Based on these prognostic variables, J.B. is a patient with a low risk of relapse. A three-drug induction regimen consisting of vincristine, dexamethasone, and pegaspargase is recommended to optimize his chances for long-term DFS.[173,176,181] Additional laboratory testing (eg, bone marrow analysis for remission and MRD) will be relied on to design his postinduction therapy.

Vincristine Toxicity

Case 95-5, Question 3: J.B. is discharged from the hospital during the second week of induction chemotherapy. Results of his CBC and differential indicate that he is responding well to his chemotherapy (ie, WBC count 2600 cells/μL, neutrophils 69%, lymphocytes 22%, platelets 229,000 cells/μL, Hct 28.6%, and lymphoblasts 0%). However, during the third week of induction chemotherapy, J.B. exhibits severe abdominal pain. It is discovered that he has not had a bowel movement in 6 days. J.B. has also been exhibiting "acting out" behaviors in recent days. How might these symptoms be explained?

The use of vincristine is associated with an autonomic neuropathy, which may substantially reduce GI motility; in severe cases, paralytic ileus may result.[182] Constipation is often accompanied by colicky abdominal pain, which may be quite distressing. These symptoms usually become apparent 3 to 10 days after drug administration and resolve over several days. Prophylactic use of a stool softener

(docusate) or laxative (polyethylene glycol) may lessen the severity of J.B.'s constipation and facilitate regular stooling. This regimen should have been instituted with his first dose of vincristine.

J.B.'s emotional changes are likely the result of the dexamethasone he is receiving. Emotional lability, sleep disturbances, depressed mood, and listlessness have occurred during corticosteroid therapy in children with ALL.[183] These behavioral changes can be quite disruptive, and parents should be prepared for them in advance. Behavioral disturbances typically resolve within 2 weeks after corticosteroid discontinuation.[162]

INTRATHECAL CHEMOTHERAPY PROPHYLAXIS

Case 95-5, Question 4: In addition to the aforementioned drugs, J.B. also receives intrathecal (IT) chemotherapy for CNS prophylaxis with methotrexate at the beginning (week 1) and end (week 4) of induction therapy. What is the purpose of IT chemotherapy?

IT or CNS preventive therapy decreases the chance of relapse within the CNS and improves J.B.'s chance of long-term survival. Before CNS preventive therapy was routine, the CNS was the most common site of leukemic relapse and, thus, predicted bone marrow relapse.[17,27,184–186] Because many antileukemic agents do not distribute well into the CSF, this area becomes a sanctuary site for leukemic lymphoblasts. The aim is to eradicate any CNS leukemic lymphoblasts present at diagnosis and to prevent the emergence of a relapse within the CNS.

Central nervous system preventive therapy options

Case 95-5, Question 5: What are the various treatments available for CNS preventive therapy for J.B.?

All treatment protocols for childhood ALL use some form of CNS preventive therapy, although different regimens are used. The first

successful CNS prophylaxis treatments were 2400 cGy of craniospinal radiation with or without IT methotrexate, which markedly reduced the CNS relapse rate.[17] However, the adverse effects of cranial irradiation were problematic. These included decreased intellectual function, dysfunctions of the neuroendocrine system, and poorer psychosocial functioning. As a result, clinicians sought alternative, potentially safer forms of CNS preventive therapy. Several trials demonstrated effective CNS prevention utilizing systemic plus IT chemotherapy without additional cranial radiation.[184,185,188] Currently, CNS preventive therapy for most patients will include IT methotrexate, triple IT chemotherapy (methotrexate, cytarabine, and hydrocortisone), or IT methotrexate combined with systemic dose–intensified methotrexate, whereas cranial radiation is reserved for only those at highest risk of CNS relapse.

Intrathecal chemotherapy: chronic adverse effects

Case 95-5, Question 6: What are the late adverse effects associated with J.B.'s IT chemotherapy?

The chronic toxicities of IT chemotherapy are difficult to fully evaluate because of the myriad of systemic chemotherapy agents also used in these patients.[17] Although less toxic than cranial irradiation, evidence suggests that IT chemotherapy is associated with some neuropsychologic deficits. At least one study of patients receiving IT chemotherapy without cranial irradiation has demonstrated deficits in higher-order cognitive function tasks and learning disabilities in mathematics. Children who are treated with IT chemotherapy before age 5 years are more likely to experience deficits in the cerebellar-frontal brain subsystem and in neuropsychologic performance. It is unclear whether these deficits translate into significant long-term consequences.

Case 95-5, Question 7: J.B. is at a low risk for CNS relapse, and the decision is made to treat him with IT methotrexate. What dose of IT methotrexate should J.B. receive?

Intrathecal methotrexate dose

High chemotherapy concentrations can be attained within the CSF with relatively low doses because the CSF volume of distribution is small in contrast to the peripheral plasma volume. Drug exposure is also maximized by the longer half-life of most drugs in the CSF.[187] The approach used for IT dosing differs from systemic administration, the latter of which is based on body weight or body surface area. CSF methotrexate concentrations appear to correlate better with patient age than size.[188] The CSF volume in children approaches that of an adult by age 3 years. Because CSF volume does not correlate with body surface area, IT doses based on body size result in subtherapeutic concentrations in young children and potentially toxic concentrations in older children and adults. The age-based dosing regimens shown in **Table 95-5** are less neurotoxic and are associated with a lower rate of CNS relapse than doses based on size.[188] Using this dosing regimen, J.B.'s dose of IT methotrexate should be 12 mg. If triple IT therapy were used, the doses of IT cytarabine and hydrocortisone would be 24 and 12 mg, respectively.

Table 95-5
Representative Dosage Regimen for Intrathecal Chemotherapy Based on Patient Age

Patient Age (years)	Methotrexate (mg)	Hydrocortisone (mg)	Cytarabine (mg)
>1	6	6	12
1	8	8	16
2	10	10	20
3	12	12	24
≥9	15	15	30

Dangers of intrathecal vincristine

Case 95-5, Question 8: J.B.'s IT methotrexate is to be administered on the same day as his vincristine dose. Are there any special precautions that should be taken when these medications are administered in close proximity?

Inadvertent administration of vincristine into the IT space is almost uniformly fatal.[189] Despite widespread educational efforts in hospitals and clinics, and numerous precautionary measures, deaths from the inadvertent IT administration of vincristine still occur. The clinical course in patients mistakenly given IT vincristine has typically progressed from backache and headache on day 1, muscle weakness (generalized) on day 2, apnea on day 5, loss of evidence of electroencephalographic activity by days 7 to 9, and death on day 12. To avoid the tragedy of IT vincristine administration, vincristine should be mixed as a small volume parenteral (ie, minibag) rather than in a syringe, and delivered to an area separate from the administration of IT medications. The Institute for Safe Medication Practices (ISMP) has called on pharmaceutical manufacturers and the Food and Drug Administration (FDA) to modify package labeling to include preparation in a minibag and remove syringe administration information.

TAILORING OF POSTINDUCTION THERAPY

CASE 95-5, QUESTION 9: An analysis of the chromosomes from J.B.'s bone marrow reveals the ETV6-RUNX1 translocation and a DNA index of 1.0. His day-29 bone marrow biopsy has no detectible blasts with MRD of 0.15%. Based on his day-29 (end of induction) bone marrow–positive MRD finding, J.B. is scheduled to receive a more aggressive postinduction chemotherapy regimen. This treatment is chosen because MRD findings are more predictive of the chance for relapse than are his cytogenetics. Although his bone marrow on day 29 indicated a complete morphologic remission, his MRD findings take precedence in defining his further therapy. After completion of the induction phase, J.B. is scheduled to receive an intensified phase of postinduction chemotherapy known as augmented interim maintenance. What is the purpose of postinduction treatment and what are some examples of effective regimens for this phase of treatment?

Postinduction chemotherapy consists of a variety of combinations of chemotherapy typically given on a 2- to 6-week treatment cycle. These different phases of postinduction therapy are known as consolidation, interim maintenance, and delayed intensification. Chemotherapy agents used will include many of the same drugs already used in induction, as well as the addition of methotrexate, cytarabine, thiopurines such as mercaptopurine and thioguanine, cyclophosphamide, and doxorubicin.

Postinduction treatment has proven to be an important strategy for the prevention of relapse in children with ALL and has helped produce event-free survival of >90% in low-risk childhood ALL.[27] To date, the optimum postinduction regimens have yet to be determined, and this remains an area of focused research. A comparison between high-dose methotrexate 5 g/m^2 IV every 2 weeks for four doses and escalating "Capizzi" dose methotrexate (every 10 days, increase by 50 mg/m^2 until toxicity is seen) showed improved 5-year event-free survival (EFS) (79.6% vs 75.4% P = .008) and no increased toxicity in high-risk patients with ALL. In fact, there was a lower incidence of febrile neutropenia in the high-dose methotrexate group compared to the escalating-dose group; 5.1% versus 8.3% respectively (P =.003).[22] Therefore, J.B. would benefit from inclusion of high-dose methotrexate as postinduction treatment.

MAINTENANCE CHEMOTHERAPY REGIMENS

Case 95-5, Question 10: After completion of his induction and postinduction chemotherapy, J.B. is scheduled to receive maintenance (also called continuation) treatment for a total therapy duration of 2 years from the start of his postinduction therapy. His parents question why treatment will be of such a long duration and ask whether this is necessary because J.B. is already in remission. What is the purpose of J.B.'s maintenance treatment for ALL? Which agents should be used in J.B. for this phase of therapy?

Maintenance treatment sustains the complete remission achieved from induction chemotherapy. Early trials have shown that without maintenance treatment, the majority of patients with ALL will relapse.[190] Patients who have successfully responded to induction and postinduction therapy may still have a leukemic cell burden (although undetectable), which must be eradicated by additional treatment. This is supported by the results of bone marrow biopsies from patients who have experienced relapse after several months to years of treatment. The cytogenetic characteristics of the leukemic cells in relapsed patients demonstrate changes similar to those at the time of diagnosis.[191] Maintenance therapy is also supported by the results of MRD studies, which demonstrate that some amount of measurable leukemic cells are still present months after the completion of induction therapy.[170]

Drugs that are effective during induction therapy cannot, by themselves, sustain remission during maintenance therapy.[153,158,194] However, other agents are effective in sustaining a complete remission. Two of the most effective drugs are mercaptopurine and methotrexate. Methotrexate is most effective and least toxic when administered intermittently, usually on a weekly basis in oral doses of 20 mg/m^2/week. Mercaptopurine is effective and well-tolerated orally when dosed daily, usually at a dose of 50 to 75 mg/m^2/day.[192]

Other agents have been added to standard maintenance therapy with mercaptopurine and methotrexate to improve remission duration and to increase a patient's chances for long-term survival. There is evidence that every 4- to 12-week pulses of vincristine and prednisone offer advantages (lower bone marrow and testicular relapse rates) in standard-risk patients as well. At present, most

contemporary treatment regimens for childhood ALL have intensified induction and postinduction phases during approximately the first 6 months. These early intensive treatments typically are followed by a less-intensive maintenance therapy consisting of methotrexate and mercaptopurine in combination with periodic IT chemotherapy treatments, either with or without intermittent vincristine and prednisone or dexamethasone pulses.[27,158]

The available evidence suggests that a patient like J.B. with standard-risk ALL will benefit from use of daily mercaptopurine 50 to 75 mg/m^2 orally (PO) and weekly methotrexate 20 mg/m^2 PO or IV, along with periodic pulse therapy with vincristine 1.5 mg/m^2 for 1 day and either prednisone 40 mg/m^2 or dexamethasone 6 mg/m^2 PO for 7 days every 4 to 12 weeks. In addition, IT methotrexate should be repeated every 8 to 12 weeks. Depending on the specific treatment protocol, his maintenance therapy will continue for ~18 to 24 months.[192]

Mercaptopurine adherence and metabolism

Case 95-5, Question 11: After 8 weeks of maintenance therapy with the regimen, the medical team notices J.B. has maintained an ANC within the normal range for more than 6 weeks, while most patients have mild count suppression on this therapy. Other hematologic and chemistry findings are also within normal limits. What are potential problems with mercaptopurine and methotrexate that could explain his ANC values? What if his ANC values were unexpectedly low?

Significant interpatient variability in absorption and metabolism of mercaptopurine have been described, which may explain the varied response among patients to standard doses.[193] Thiopurines, including mercaptopurine and thioguanine, are inactivated by the enzymes thiopurine-*S*-methyltransferase (TPMT) and nudix hydrolase 15 (NUDT15).[194] Although most patients have normal activity of these enzymes, deficient TPMT activity can be seen in up to 10% of the population, with the highest incidence in those of African or European descent.[194] This same population is more likely

to have normal NUDT15 activity, whereas up to 20% of patients of Asian or Hispanic ethnicity have abnormal NUDT15.[194,195] Patients with deficient TPMT or NUDT15 activity experience severe and even fatal toxicity with standard mercaptopurine doses and require very low doses (~10 mg/m^2 three times/week) to avoid profound myelosuppression.[194]

In fact, many centers send genetic testing prior to the initiation of thiopurines to identify polymorphisms with TPMT and NUDT15. This allows for pre-emptive dose adjustments to mercaptopurine in patients who are expected to have slowed metabolism. **Figure 95-1** shows suggested thiopurine dosing for patients predicted to be intermediate or poor metabolizers based on genotyping.[194]

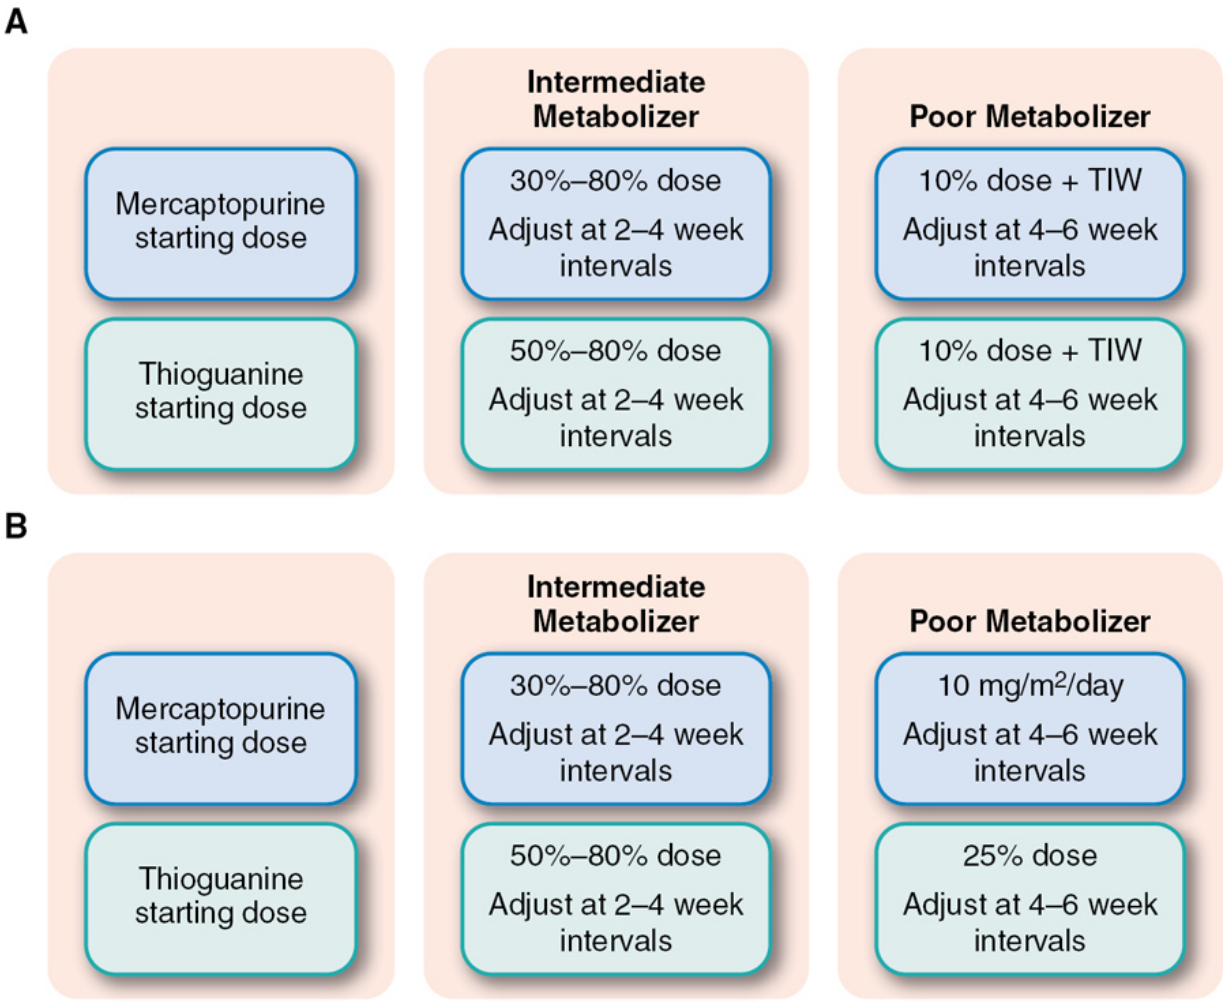

Figure 95-1 Pharmacogenomic dosing of thiopurines. A, Recommended thiopurine dose for abnormal TPMT activity. B, Recommended thiopurine dose for abnormal NUDT15 activity. TIW, three times weekly. TMPT, thiopurine-*S*-methyltransferase. (From Relling M, Schwab M, Whirl-Carrillo M, et al. Clinical Pharmacogenetics Implementation Consortium guideline for thiopurine dosing based on TPMT and NUDT15 genotypes: 2018 update. *Clin Pharmacol Ther*. 2019;105(5):1095–1105.)

Another possible explanation for J.B.'s normal ANC could be nonadherence with the oral chemotherapy agents at home. As with any medication, poor adherence to oral chemotherapy has been associated with inferior outcomes.[196] In a study of 298 pediatric patients with ALL, mercaptopurine adherence rates below 90% were associated with a 3.9-fold increase in risk of relapse.[197] A thorough discussion should be had with J.B.'s care providers to determine how many doses of oral chemotherapy have been missed and to discuss barriers to adherence if they do exist.

Asparaginase

Asparaginase is an important addition to ALL therapy. In the 1980s, the addition of L-asparaginase to treatment of childhood ALL increased survival rates by 10% or more.[198,199] There are multiple products available, derived from one of two natural sources, *Escherichia coli* and *Erwinia chrysanthemi.* Pegaspargase is a pegylated long-acting form derived from *E. coli*. The incidence of hypersensitivity reactions to available products varies from 11% to 33% or higher.[198,200] Asparaginase preparations are not 100% cross-reactive, so the *Erwinia* product may be substituted for the *E. coli* product when hypersensitivity reactions occur. Of major concern, some patients may develop antibodies to these foreign proteins, which quickly inactivate the enzymes.[200] In up to 30% of children, this inactivation is "silent" and not accompanied by an occult hypersensitivity reaction.[199,200] To screen patients for silent inactivation, routine monitoring of asparaginase activity levels

following each dose of asparaginase has become a useful tool.[199] In cases where insufficient asparaginase activity is noted, the patient may be switched to another source product for future doses. Although several studies have correlated sufficient asparaginase activity with improved clinical outcomes, the goal activity level has varied between trials.[201–203] The COG has adopted a goal trough asparaginase activity level ≥0.1 IU/ ml based on a recently published consensus statement.[199,204]

Targeted therapies for ALL

As mentioned earlier in the discussion of cytogenetic variables in ALL, patients with t(9,22)/BCR-ABL1 translocation have a more difficult path to achieving a lasting remission.[166,205] The tyrosine kinase inhibitors imatinib and dasatinib have both been studied in combination with chemotherapy in this patient population and dramatically improved treatment outcomes. Prior to tyrosine kinase inhibitors, patients with the t(9,22) translocation required stem cell transplant. However, recent trials demonstrated 70% DFS with chemotherapy plus either dasatinib or imatinib, which was similar to outcomes with stem cell transplant. Less is known about the use of the other second- and third-generation tyrosine kinase inhibitors in children, although adult data have established a role in patients with inferior response to the aforementioned agents. In addition to targeted agents, children with t(9,22) will received more intensive chemotherapy as compared to standard ALL therapy.

Patients with T-cell ALL have a difficult time achieving remission and require intensified induction and consolidation chemotherapy regimens. In addition to intensified chemotherapy, nelarabine is approved for high risk or relapsed T-ALL. Nelarabine is a nucleoside analog and functions as a false purine inhibiting DNA synthesis within T cells. It gained FDA approval based on response rates observed in two trials of relapsed and refractory patients.[206,207] These trials both noted minimal hematologic toxicity, whereas neurologic toxicity was observed to be dose-limiting. A randomized trial of high-risk pediatric patients with T-ALL compared nelarabine to standard

chemotherapy and noted neurologic toxicity was similar between groups, with a significant DFS advantage in the nelarabine group.[208,209]

Relapsed Acute Lymphoblastic Leukemia

Prognosis

CASE 95-6

QUESTION 1: N.B. is a 12-year-old male with B-cell ALL. Initially, he responded to therapy and achieved a complete remission. However, about 17 months after his initial diagnosis, N.B. undergoes a routine lumbar puncture as part of his planned maintenance therapy. Analysis of the CSF indicates the presence of numerous lymphoblasts. A CBC reveals the following:

Hct, 29.5%
Platelet count, 120,000 cells/μL
WBC, 5300 cells/μL, with 45% lymphocytes, 50% neutrophils, and 5% bands
A bone marrow biopsy confirms relapsed ALL with 53% lymphoblasts.

What are N.B.'s chances of achieving a second remission and long-term survival? Are there specific features about N.B.'s relapse that confer a worse prognosis?

N.B. is asymptomatic at the time of relapse, as are most patients experiencing a relapse of ALL. Most of these patients are diagnosed by routine CBCs or lumbar punctures. Although patients with ALL typically have excellent responses to treatment after relapse, many patients will relapse again, and 50% to 60% will not be long-time survivors.[210,211] N.B.'s relapse would be described as an early marrow relapse because it occurred <36 months from his initial diagnosis. Patients with an early marrow relapse can expect to achieve a second remission 83% of the time, as compared to 93% of patients who relapse at 36 months or later.[211] MRD data are collected in these patients achieving a second remission and is helpful in predicting patient who may benefit from intensified relapse therapy.[212]

TREATMENT OF RELAPSED ACUTE LYMPHOBLASTIC LEUKEMIA

CASE 95-6, QUESTION 2: Which treatments could be used to attain a complete remission and improve N.B.'s chances of long-term survival?

Salvage therapy for relapsed ALL is individualized based on patient-specific and disease-specific factors, including time to relapse, site(s) of relapse, immunophenotype, and response to reinduction therapy. Agents used in salvage regimens are similar to those used in high-risk ALL regimens. In general, treatment usually consists of an intensive four-agent induction regimen of vincristine, steroid, daunorubicin or mitoxantrone, and asparaginase.[212,213] After this regimen has been completed, patients may continue with courses of intensification chemotherapy, targeted agents, or cellular therapy.

In N.B.'s case, his regimen should include intensive therapy, preferably with drugs and regimens to which he has not been previously exposed, because his relapse occurred while he was on therapy. Targeted therapy with blinatumomab may provide N.B. with an improved chance of cure. In clinical trials of relapsed or refractory patients like N.B., complete response rates above 40% were reported.[214–217] Conversion to MRD-negative marrow was observed in patients who were MRD-positive after reinduction chemotherapy.[218–220] Blinatumomab is a bispecific anti-CD3/anti-CD19 monoclonal antibody. Healthy T cells are activated by binding CD3 and then attack CD19-positive B cells, including the leukemia cells. Although drug delivery is complicated and involves a 28-day continuous infusion, the incidence of grade III or greater adverse events in clinical trials was less common with blinatumomab than chemotherapy. Patients are at risk for cytokine release syndrome and neurologic adverse events including encephalopathy or seizure.[220,214]

Case 95-6, Question 3: N.B.'s family is quite concerned about the poor prognosis associated with his relapse and inquire about the role of hematopoietic cell transplantation (HCT) in his relapse treatment. Should he be considered for HCT at this point? What other cellular therapies might be an option for N.B?

Allogeneic HCT provides the best chance of cure for children with relapsed ALL who have high-risk and intermediate-risk features.[221,222] N.B.'s family should be offered the option of allogeneic HCT, and his family should be tested for an appropriate sibling match as this offers lower morbidity than an unrelated donor. Because his outcome in transplant improves if performed during a second complete remission, he should begin reinduction chemotherapy, while HCT is being arranged. If HCT does not prove to be a feasible option for N.B., novel therapies may be considered.

New to the field of cellular therapy, CAR T-cell products involve harvesting T cells from the patient, then adding a chimeric T-cell receptor to target the cancer cell, in this case CD19.[223–225] Tisagenlecleucel is a CD19-directed CAR T-cell product with approval in pediatric patients with relapsed or refractory B-cell ALL. In clinical trials, 80% to 90% of patients treated experienced a complete marrow response, with adverse reactions including cytokine release syndrome and neurologic toxicity similar to blinatumomab. These engineered T cells are expected to proliferate and survive for a significant period of time, helping to prevent future relapses. Although therapy with CAR T cells was developed as consolidation prior to stem cell transplant, some patients demonstrate long-term remissions without having received subsequent stem cell transplant.

PEDIATRIC NON-HODGKIN LYMPHOMA

Lymphomas are a collection of diseases originating in cells and organs of the immune system. Lymphomas account for ~10% to

15% of all childhood malignancies, and they are less common in children than in adults. The malignancy can occur in any lymphoid cell at any level of differentiation and appears to be a consequence of a genetic alteration. Non-Hodgkin lymphoma (NHL) is the most common form of lymphoma in children younger than age 10 years, whereas Hodgkin lymphoma is most common in children ages 15 to 19 years. This section will focus on NHL. Considerable progress has been made in the treatment of children with NHL and more than 80% of children are cured.[226]

Classification

Pediatric NHLs are best classified using histopathology, which divides them into three different categories: mature B-cell lymphomas, lymphoblastic lymphomas, and anaplastic large-cell lymphomas.[227] This is a narrower range of histologic types than in adults.

Lymphoblastic lymphomas account for ~25% of childhood NHLs, B-cell lymphomas for about 65%, and anaplastic large-cell lymphomas for the remainder.[226] The lymphoblastic lymphomas are usually immature T cells that are histologically identical to the cells of ALL. The distinction between lymphoblastic lymphoma and ALL is made on the basis of bone marrow involvement, with ALL being diagnosed if there is >25% bone marrow infiltration. B-cell lymphomas may be further divided into Burkitt, primary mediastinal, and large B-cell lymphomas. Anaplastic large-cell lymphomas may be T cell or null cell in origin.[227,228]

Clinical Presentation

Pediatric patients with NHL may present with a number of different symptoms, many of which are related to the type of NHL.[226,227] In general, these symptoms differ from those in adults because of the propensity of pediatric NHLs to be extranodal in origin in contrast to the common nodal presentation of adult NHL. Patients with

lymphoblastic lymphoma commonly present with a mediastinal mass or pleural effusions. They also may have pain, dyspnea, or swelling of the face and upper arms if superior vena cava obstruction is present. Lymphoblastic lymphoma also has a predilection for the bone marrow and the CNS. Patients with B-cell NHL typically present with an abdominal tumor, abdominal pain, an alteration in bowel function, and possibly nausea and vomiting. In addition, many patients with B-cell NHL present with bone marrow involvement. Lymphadenopathy in these patients typically occurs below the diaphragm in the inguinal or iliac area. Anaplastic large-cell lymphomas may involve the gut or unusual sites such as the lung, skin, face, or CNS.

Staging

A commonly used staging system for pediatric NHL is the St. Jude or Murphy staging system.[229] It includes four stages, with stage I being a single tumor or a single nodal area, and higher stages including cases with regional involvement or more than one anatomical site involved. The highest stage (stage IV) refers to patients with bone marrow or CNS involvement. A Revised International Pediatric Non-Hodgkin Lymphoma Staging System has recently been developed to incorporate newly identified histologic entities and advanced imaging.[230,231] The main predictor of outcome in pediatric patients with NHL has historically been determined by tumor burden at presentation. However, with modern chemotherapy regimens that are tailored to the extent of disease, patients with higher-stage disease may achieve a similar event-free survival to that achieved in patients with lower-stage disease.[226]

Overview of Treatment

Lymphoblastic (T Cell) Lymphomas

The primary treatment for all stages and histologic types of pediatric NHL is combination chemotherapy utilizing the wide variety of

chemotherapy agents that have activity in childhood NHL. Nearly 90% of lymphoblastic lymphoma in children will be of T-cell origin, thus treatment of this disease is focused primarily on the T-cell subset.[232] At present, the best results for T-cell lymphoblastic lymphoma treatment are based on the backbone by the Berlin–Frankfurt–Muenster **(**BFM) group, with an estimated 5-year event-free survival of ~85% (**Table 95-6**).[233,234] This regimen uses an intensive scheme of multiagent chemotherapy administered over 24 months. Patients with lymphoblastic lymphoma require longer treatment duration than patients with B cell or anaplastic large-cell lymphoma. This chemotherapy plan is similar to that used in the treatment of ALL and includes CNS preventive therapy regardless of stage. Much like ALL, the use of cranial radiation has been replaced with intrathecal chemotherapy and CNS-active agents such as methotrexate and cytarabine.[232,233,234]

Table 95-6

Berlin–Frankfurt–Muenster (BFM) Group Treatment Protocols for T-Cell Lymphoblastic Lymphoma

Drug	Dose	Days of Administration
Induction Protocol I (All Stages)		
Prednisone (PO)	60 mg/m^2	1–28, then taper
Vincristine (IV)	1.5 mg/m^2 (max 2 mg)	8, 15, 22, 29
Daunorubicin (IV over 1 hour)	30 mg/m^2	8, 15, 22, 29
L-Asparaginase (IV[a] over 1 hour)	10,000 IU/m^2	12, 15, 18, 21, 24, 27, 30, 33
Cyclophosphamide (IV over 1 hour)	1000 mg/m^2	36, 64
Cytarabine (IV)	75 mg/m^2	38–41, 45–48, 52–55, 59–62
6-Mercaptopurine (PO)	60 mg/m^2	36–63
Methotrexate (IT)[b]	12 mg	1, 15, 29, 45, 59
Protocol M (Typically Stages I and II)		

Drug	Dose	Days of Administration
Induction Protocol I (All Stages)		
Mercaptopurine (PO)	25 mg/m^2	1–56
Methotrexate (IV)	5 g/m^2	8, 22, 36, 50
Methotrexate (IT)	12 mg	8, 22, 36, 50
Reinduction Protocol II (Stages III and IV Only)		
Dexamethasone (PO)	10 mg/m^2	1–21, then taper
Vincristine (IV)	1.5 mg/m^2 (max 2 mg)	8, 15, 22, 29
Doxorubicin (IV over 1 hour)	30 mg/m^2	8, 15, 22, 29
L-Asparaginase (IV[a])	10,000 IU/m^2	8, 11, 15, 18
Cyclophosphamide (IV over 1 hour)	1000 mg/m^2	36
Cytarabine (IV)	75 mg/m^2	38–41, 45–48
Thioguanine (PO)	60 mg/m^2	36–49
Methotrexate (IT)	12 mg	38, 45
Maintenance (All Stages)		
Mercaptopurine (PO)	50 mg/m^2	Daily until month 24 of therapy
Methotrexate (PO)	20 mg/m^2	Weekly until month 24 of therapy

Note: IT methotrexate doses were adjusted for children younger than 3 years. Ten percent of the 5 g/m^2 methotrexate dose in protocol M was given for 30 minutes, and 90% was given as a 23.5-hour continuous IV infusion. Leucovorin rescue: 30 mg/m^2 IV at hour 42; 15 mg/m^2 IV at hours 48 and 54.

CNS, central nervous system; IT, intrathecally; IV, intravenously; PO, orally.

[a]This agent is substituted with pegaspargase 2500 units/m^2 in the United States based on drug availability.

[b]Additional intrathecal chemotherapy doses are given on days 8 and 22 for CNS-positive patients.

Source: Reiter A, Schrappe M, Ludwig WD, et al. Intensive ALL-type therapy without local radiotherapy provides a 90% event-free survival for children with T-cell lymphoblastic lymphoma: a BFM group report. *Blood*. 2000;95(2):416–421. © 2000 American Society of Hematology. With permission.

The BFM backbone has been modified in recent years to replace L-asparaginase with pegaspargase and replace prednisone with dexamethasone during induction. Additionally, T-cell lymphoblastic lymphoma patients are treated with escalating (Capizzi) methotrexate regimen in place of high-dose methotrexate during consolidation. The benefit of adding nelarabine to this modified BFM backbone is unclear but is being explored in clinical trials.[232,233,234]

B-CELL LYMPHOMAS

Treatment of mature B-cell lymphomas differs from lymphoblastic lymphoma in both duration and agents used.[226] The trend in B-cell lymphoma treatment has been toward short-duration, intensive therapy with alkylating agents in conjunction with high-dose antimetabolite therapy (eg, methotrexate, cytarabine). Chemotherapy is administered in rapid succession with limited recovery from neutropenia (ie, ANC 500 cells/μL) between cycles.

Patients are classified into risks groups A, B, and C based on disease stage, resectability, and presence of CNS or bone marrow involvement. Those in the lowest risk category A require only two or three cycles of COPAD regimen consisting of cyclophosphamide, vincristine, doxorubicin, and prednisone.[226] In this group with localized disease, maintenance chemotherapy did not demonstrate any added benefit and should not be offered.[235,236] Contemporary chemotherapy regimens include varying degrees of treatment intensity from three to seven cycles, depending on whether the tumor is completely resected, bone marrow and CNS involvement, and the serum LDH.[237,238]

With the addition of high-dose methotrexate, etoposide, and cytarabine to the standard regimen, patients with stage III and IV disease are now achieving survival rates comparable to those of patients with limited-stage disease.[239] Patients with bone marrow disease also benefit from these intensive therapeutic strategies and have achieved impressive survival rates of ~90%. Currently, patients with advanced-stage disease are treated with a total of six to eight cycles of chemotherapy, and these treatment protocols achieve

superior results to those of a much longer duration (eg, 1–2 years) used previously. The addition of rituximab to chemotherapy for B-cell lymphomas prolongs event-free survival; however, it increases the incidence of infection and hypogammaglobulinemia.

ANAPLASTIC LARGE-CELL LYMPHOMAS

Anaplastic large-cell lymphomas have responded well to both types of regimens.[237] Thus, the use of shorter, less complicated, B-cell protocols is appropriate. Targeted agents such as crizotinib in ALK-positive tumors and brentuximab vedotin in tumors that express CD30 are subjects of current research.[237,238] Patients who fail to respond may be treated with additional courses of their prescribed protocol in hopes of eventually inducing a response. Patients who relapse may be reinduced with intensive chemotherapy, but their prognosis for long-term survival is unfavorable.[237]

Lymphoblastic Lymphoma

Acute Treatment

CASE 95-7

QUESTION 1: D.B., a 16-year-old female, presents with a history of shortness of breath and chest pain for 3 weeks. A mediastinal mass is found, and a biopsy confirms lymphoblastic (T cell) lymphoma. Laboratory values show the following results:

Erythrocyte sedimentation rate, 35 mm/hour
WBC count, 22,000 cells/μL
Uric acid, 7 mg/dL
LDH, 1259 units/L

The bone marrow, CNS, and abdomen are negative for lymphoma.

How should D.B. be managed acutely? Besides chemotherapy, what types of adjunctive therapies should be initiated to minimize the acute effects of treatment?

Given D.B.'s shortness of breath and chest pain, it is likely that her mediastinal mass may be obstructing the superior vena cava. To

alleviate this obstruction, the most appropriate course of action is to decrease the tumor mass by initiating chemotherapy as soon as possible. Radiation therapy offers no additional benefit in patients like D.B., with a tumor such as NHL, which is highly responsive to chemotherapy.[232] Because of the rapid cell kill that will result from the initiation of chemotherapy, tumor lysis syndrome and uric acid nephropathy are possible.

Aggressive hydration and allopurinol should be instituted before chemotherapy to prevent tumor lysis syndrome. Because D.B. has a pleural effusion, fluids may collect in this third space, resulting in weight gain and decreased urine output. Thus, in addition to placement of a chest tube with suction, D.B. should be given diuretics to maintain an adequate urine output. To minimize intravascular volume depletion and maintain electrolyte balances, fluid input and output, body weight, and electrolytes should be monitored daily. These values should be used to make appropriate adjustments in D.B.'s electrolyte and fluid balance. See Chapter 96, Adult Hematologic Malignancies, for a complete discussion of tumor lysis syndrome.

Adverse effects

Case 95-7, Question 2: D.B. is treated with the BFM combination chemotherapy regimen. Because of her intrathoracic mass, her disease is characterized as stage III. She is to receive induction therapy (Induction Protocol I) for 8 weeks, as outlined in Table 95-6. Which acute adverse effects is D.B. likely to experience with these agents? How can they be monitored, minimized, and treated?

Several toxicities are expected with these chemotherapy agents. For vincristine, both constipation and neuropathy are likely to appear during or after the 4 weeks of therapy.[182] Constipation can be prevented or minimized by use of stool softeners with or without a laxative. Neuropathy may be painful (especially when jaw pain occurs) but can be managed with mild analgesic regimens consisting of NSAIDs or acetaminophen. Both toxicities are self-limiting and are

not reasons to discontinue or decrease the dosage of vincristine unless neuromuscular toxicity, as evidenced by motor weakness, develops. The incidence of jaw pain and foot drop is higher in pediatric populations as compared to adults. Asparaginase can cause several types of toxicities (eg, hypersensitivity reaction, coagulation disorders, pancreatitis), most of which are not thought to be preventable.

Prednisone is likely to increase D.B.'s appetite and may cause gastritis, although divided doses will help decrease stomach upset. In addition, prednisone-induced behavioral disturbances, such as hyperactivity, are common in children.[183] Unlike prednisone and vincristine, daunorubicin, cyclophosphamide, cytarabine, and mercaptopurine produce significant myelosuppression. Leukopenia is common with the nadir occurring in ~8 to 14 days, and recovery occurring by approximately day 21 after administration. Because the goal of induction therapy is achievement of remission, doses of daunorubicin will not be held for uncomplicated myelosuppression during the first 4 weeks of induction therapy, although during the latter 4 weeks, the combination of cyclophosphamide, cytarabine, and mercaptopurine are typically held until hematologic recovery occurs.

Hemorrhagic cystitis may occur with cyclophosphamide, but it is usually associated with high-dose therapy or with prolonged administration, which D.B. is not receiving. Vigorous IV hydration to maintain urine output of ~50 to 100 mL/m^2/hour should reduce the risk of this toxicity. Because most of the induction regimen will be administered on an outpatient basis, patients or parents should be instructed to report signs or symptoms of infection (eg, febrile episodes) immediately so that proper treatment may be instituted as soon as possible. To decrease the risk of hemorrhagic cystitis, parents should be instructed to report whether patients are urinating regularly after cyclophosphamide. See Chapter 94, Adverse Effects of Chemotherapy, Immunotherapy, and Targeted Agents, for further discussion of these adverse effects.

Nausea and vomiting are likely to be induced by daunorubicin, cyclophosphamide, and cytarabine. D.B.'s chemotherapy regimen

includes a corticosteroid (prednisone), which may provide some antiemetic activity during the initial 4 weeks. However, to maximize tolerance to her chemotherapy, D.B. should receive a 5-HT_3 serotonin antagonist. D.B. is unlikely to require additional corticosteroids during the first 4 weeks of induction therapy. However, during the second portion of induction, D.B. will benefit from a few doses of dexamethasone at the time of cyclophosphamide administration.[240] See Chapter 22, Nausea and Vomiting, for further discussion of chemotherapy-induced nausea and vomiting.

Central nervous system prophylaxis

Case 95-7, Question 3: What is the importance of CNS prophylaxis for D.B. and what type of treatment regimen is typically used?

All pediatric patients with lymphoblastic lymphoma should receive some form of CNS prophylaxis. Although lymphoblastic lymphoma rarely presents with CNS involvement, as illustrated by D.B., it was a common site of relapse before CNS prophylaxis was included as a routine part of the chemotherapy regimen.[232] Recurrence of NHL within the CNS is rare when IT methotrexate or cytarabine is given.[234] D.B. will be treated with IT methotrexate periodically, as outlined in Table 95-6.

Myelosuppression and hematopoietic recovery

Case 95-7, Question 4: After completion of induction therapy, the chemotherapy plan for D.B. consists of protocol M and reinduction protocol II, as outlined in Table 95-6. How should D.B.'s hematopoietic recovery be managed, and what guidelines may be used to determine when it is appropriate for her to receive the next sequence of the treatment cycle? Would D.B. benefit from a colony-stimulating factor to aid with hematopoietic recovery?

This aggressive combination of chemotherapy agents will result in significant myelosuppression. Similar to Induction protocol I, dosing of chemotherapy will not be held for uncomplicated myelosuppression. However, before initiating the second phase on day 36, clinicians will assure adequate hematologic recovery, typically defined as an ANC >750 cells/μL and platelets >100,000 cells/μL. It is unlikely that D.B. will benefit from a colony-stimulating factor during these phases of therapy. When myelosuppressive chemotherapy is given fairly continuously, as is the case with protocol II, there is little room for inserting doses of colony-stimulating factors on days where myelosuppressive chemotherapy is not being administered.

Adult Hematologic Malignancies

Casey B. Williams, Rachel Elsey, Sarah M. Hayes, and Jacob K. Kettle

CORE PRINCIPLES	CHAPTER CASES
ACUTE MYELOID LEUKEMIA	
1 Acute myeloid leukemia (AML) generally appears suddenly and progresses rapidly. Death as a result of infection or bleeding occurs within weeks to months if the patient is not effectively treated.	**Case 96-1 (Questions 1, 2)**

CORE PRINCIPLES		CHAPTER CASES
2	Although >60% of patients treated for AML achieve complete remission after induction therapy, the median duration of the remission is only about 12–18 months, and only 20%–40% of patients have a disease-free survival (DFS) exceeding 5 years. Short remissions have been attributed to proliferation of clinically undetectable leukemic cells. Thus, the rationale for administering chemotherapy after remission is to eradicate these residual cells.	**Case 96-1 (Question 5)**
3	The incidence of AML increases with advancing age. At age 40 years, there is only 1 case of AML per 100,000, but the annual incidence increases to 15% at age older than 75 years. The prognosis of patients with AML is directly related to age.	**Case 96-1 (Question 7)**
4	Elderly patients do not tolerate intensive induction and postremission chemotherapy as well as younger patients. Older patients often have comorbid medical conditions and a poor performance status, which are associated with worse outcomes with conventional therapy.	**Case 96-1 (Question 7)**

CORE PRINCIPLES		CHAPTER CASES
5	In younger patients, failure to achieve remission or disease relapse remains the major cause of treatment failure. This reflects both the failure of current salvage regimens and the absence of effective strategies to secure long-term DFS in those patients who achieve a second hematologic remission. A wide range of salvage options have been studied, but with <50% of patients achieving a second remission and median survival ranging from 3 to 12 months, there remains considerable room for improvement.	**Case 96-2 (Question 1)**
CHRONIC MYELOGENOUS LEUKEMIA		
1	Chronic myelogenous leukemia (CML) occurs in three phases: chronic, accelerated, and blast. Most patients are diagnosed in chronic-phase CML and are asymptomatic at presentation but evaluated because of an abnormally high leukocyte count (often >100 × 10^9/L). The cytogenetic hallmark of CML is the Philadelphia (Ph) chromosomal translocation oncogene, which generates the BCR-ABL fusion protein. Quantitative assessment of BCR-ABL messenger ribonucleic acid (mRNA) transcripts in the blood is used to measure response to therapy.	**Case 96-3 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
2	Hematopoietic stem cell transplantation (HCT) is the only curative therapy for CML, but it is seldom recommended as first-line therapy for patients in chronic-phase CML. Imatinib, dasatinib, nilotinib, and bosutinib are all oral small-molecule tyrosine kinase inhibitors (TKIs) of the BCR-ABL protein and approved as first-line treatment.	**Case 96-3 (Question 3)**
LYMPHOMA		
1	Lymphomas are a diverse collection of hematologic malignancies originating from lymphoid tissues. Lymphomas are classified as either Hodgkin lymphoma (HL) or non–Hodgkin lymphoma (NHL). The NHLs can be further divided into aggressive or indolent subgroups. Symptoms include painless lymphadenopathy along with nonspecific findings of generalized malaise and fatigue. Advanced complications arise from the infiltration of the disease into extramedullary tissues including the lungs, central nervous system, and bone marrow.	**Case 96-4 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
2	HL is a B-cell neoplasm and is highly responsive to chemotherapy and often curable with modern treatments. A combination of doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) is the most frequently used chemotherapy regimen. Delayed consequences of therapy have heightened importance in the management of this disease owing to the expected long-term survival for most patients.	**Case 96-5 (Questions 1, 2)**
3	Aggressive NHLs such as diffuse large B-cell lymphoma (DLBCL) progress rapidly and are treated with intensive combination chemotherapy regimens administered with a curative intent. Chemoimmunotherapy with rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) is conventional therapy for DLBCL.	**Case 96-6 (Questions 1, 2)**

CORE PRINCIPLES		CHAPTER CASES
4	Although indolent NHLs including follicular lymphoma (FL) are generally incurable, these diseases develop slowly and are initially responsive to numerous therapies. Treatment is aimed at reducing disease burden and prolonging survival and is often reserved until the patient is symptomatic. A combination of bendamustine and rituximab (BR) is commonly used in the management of these neoplasms.	**Case 96-7 (Questions 1, 2)**

INTRODUCTION

Acute Myeloid Leukemia

Acute myeloid leukemia (AML) consists of a group of relatively well-defined hematopoietic neoplasms involving precursor cells committed to the myeloid line of cellular development.

In the United States and Europe, the incidence has been relatively stable at 3 to 5 cases per 100,000. AML is the most common acute leukemia in adults and accounts for ~80% of cases in this group of neoplasms. In contrast, AML accounts for <10% of acute leukemias in children younger than 10 years of age. AML incidence is age dependent, rising markedly in patients ages 60 years. Across all age groups, the incidence of AML is higher in males than in females.[1–3] The median age at diagnosis is ~70 years.[4]

The 2016 World Health Organization (WHO) classification identifies distinct categories of AML.[5] Notably, AML is primarily categorized by recurrent genetic abnormalities, with morphologic

classification reserved for patients not otherwise classifiable. With advanced age, the relative incidence of AML with recurrent genetic abnormalities decreases, whereas the relative incidence of other AML categories increases with age, comprising about 19% and 7% of AML cases, respectively.[6] A complete list of the WHO classification of AML can be found at https://doi.org/10.1182/blood-2016-03-643544.

Pathophysiology

AML is characterized by a clonal proliferation of myeloid precursors with a reduced capacity to differentiate into mature myeloid cells. As a result, there is an accumulation of leukemic blasts in the bone marrow (BM), peripheral blood, and occasionally in other tissues, with a variable reduction in the production of normal red blood cells, platelets, and mature granulocytes. The proliferation of malignant cells, along with a reduction in normal hematopoietic cells, results in a variety of systemic consequences including anemia, bleeding, and an increased risk of infection.

Genetic classification of AML is essential to guide clinical decisions and predict prognosis. The 2017 European LeukemiaNet and American Society of Hematology recommendations identify three risk groups, based on karyotype and mutational analysis (**Table 96-1**).[1,4,7,8] The favorable-risk AML group comprises all patients in whom a relapse risk is predicted to be low if treated with induction and consolidation alone. The intermediate-risk AML group comprises patients with molecular or cytogenetic abnormalities not classified as favorable or adverse and includes patients with *NPM1*^{mut} and a high allelic ratio of *FLT3*-ITD. The adverse-risk AML group includes patients with complex cytogenetics and other poor-risk genetic aberrations. All patients failing to achieve a complete response (CR) after two induction cycles should also be considered as adverse-risk patients, regardless of genetics/cytogenetics. Accurate risk stratification plays a critical role in guiding the selection

of the optimal postremission approach and of indications for allogeneic hematopoietic cell transplant (alloHCT) in first CR (CR1).

Table 96-1
Risk Stratification of Acute Myeloid Leukemia by Genetics

Risk Category	Genetic Abnormality
Favorable	▪ t(8;21)(q22;q22.1); *RUNX1-RUNX1T1* ▪ inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11* ▪ Mutated *NPM1* without *FLT3*-ITD or with *FLT3*-ITD^{low} ▪ Biallelic mutated *CEBPA*
Intermediate	▪ Mutated *NPM1* and *FLT3*-ITD^{high} ▪ Wild-type *NPM1* without *FLT3*-ITD or with *FLT3*-ITD^{low} (without adverse risk genetic lesions) ▪ t(9;11)(p21.3;q23.3); *MLLT3-KMT2A* ▪ Cytogenetic abnormalities not classified as favorable or adverse
Adverse	▪ t(6;9)(p23;q34.1); *DEK-NUP214* ▪ t(v;11q23.3); *KMT2A* rearranged ▪ t(9;22)(q34.1;q11.2); *BCR-ABL1* ▪ inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); *GATA2*, *MECOM (EVI1)* ▪ -5 or del(5q); -7; -17/abn(17p) ▪ Complex karyotype, monosomal karyotype ▪ Wild-type *NPM1* and *FLT3*-ITD^{high} ▪ Mutated *RUNX1* ▪ Mutated *ASXL1* ▪ Mutated *TP53*

A comprehensive risk classification integrating clinical, genetic, and treatment data is available as an online tool that simulates the individual patient's risk and predicts outcome with and without alloHCT (https://cancer.sanger.ac.uk/aml-multistage/).[9]

Clinical Presentation and Diagnosis

Patients with AML generally present with symptoms related to complications of pancytopenia (eg, anemia, neutropenia, and thrombocytopenia), including weakness and easy fatigability, infections of variable severity, and hemorrhagic findings such as gingival bleeding, ecchymosis, epistaxis, or menorrhagia. Combinations of these symptoms are common. It is often difficult to date the onset of AML precisely, at least in part because individuals have different symptomatic thresholds for seeking medical attention. It is likely that most patients have had more subtle evidence of BM involvement for weeks, or perhaps months, before diagnosis. Although a presumptive diagnosis of AML can be made by examination of the peripheral blood smear when there are circulating leukemic blasts, a definitive diagnosis usually requires a BM aspiration and biopsy. Morphologic, immunophenotypic, cytogenetic, and molecular studies must be performed in every case. The information derived from these studies is critical for making the correct diagnosis as well as determining prognosis and treatment.

Classification and Diagnosis

For a definitive diagnosis of AML, the BM aspirate must contain >20% leukemic blast cells. A normal BM aspirate would typically contain <5% blast cells.

Patients suspected of a diagnosis of AML must undergo prompt cytogenetic and molecular investigations to inform risk stratification and, increasingly, treatment strategies. It is vital to urgently differentiate acute promyelocytic leukemia (APL) from other forms of AML by cytomorphology, signs of hyperfibrinolysis, and molecular evidence of *PML-RARA* fusion.

AML is defined based on morphologic inspection revealing a myeloid blast count of ≥20% out of 500 BM cells, although counting fewer cells is sufficient in patients with high blast counts. Blast counts should include myeloblasts, monoblasts/promonocytes, and megakaryoblasts, but not abnormal monocytes. According to the latest WHO classification, all nucleated cells in the BM serve as a

denominator, even in cases where the BM is enriched with erythroid precursors.

Cells of myeloid origin commonly contain myeloperoxidase enzymes and express surface markers CD13, CD33, CD14, and CD15. Specific clonal chromosomal abnormalities are associated with several AML subtypes. These aberrations include gains or losses of whole chromosomes on the long (q) or short (p) arms, as well as a variety of structural rearrangements (eg, translocations, inversions, insertions). These findings are increasingly being used to guide treatment decisions and a full list can be found in consensus guidelines. For example, patients with cytogenetic and molecular findings associated with a poor prognosis may be considered for more aggressive postremission therapy such as high-dose chemotherapy with HCT. Other poor prognostic signs in AML include age older than 60 years at the time of diagnosis, a preexisting hematologic disorder (eg, myelodysplastic syndrome), prior exposure to a chemotherapy agent (eg, a secondary leukemia), and poor baseline performance status.

Signs and Symptoms

CASE 96-1

Question 1: C.C., a 58-year-old male, presented to the emergency department with increasing fatigue and fever and an inability to eat. This past week, a peripheral blood smear (complete blood count [CBC]) revealed a white blood cell (WBC) count of 160,000 cells/μL with a differential of >90% leukemic blasts (normal, 0%), a hemoglobin (Hgb) of 7.5 g/dL, and a platelet count of 42,000 cells/μL. A BM aspirate and biopsy confirmed the diagnosis of AML (60% blasts, myeloperoxidase positive; CD13 and CD33 positive). All serum chemistry values were within normal limits, with the exception of potassium (K), 3.1 mEq/L; phosphorus, 5.5 mg/dL; and lactate dehydrogenase (LDH), 3500 units/mL. Physical examination was remarkable for oral leukoplakia from oral candidiasis and poor dentition.

Which signs and symptoms exhibited by C.C. are consistent with AML?

C.C.'s symptoms of increasing fatigue and fever of 1 week's duration are consistent with a rapid reduction in red blood cells leading to anemia (Hgb, 7.5 g/dL) and a low neutrophil count leading to infection (oral candidiasis). Although his WBC count is high, the differential reveals that >90% are blasts, which are immature, nonfunctional cells of myeloid or lymphoid origin. Circulating blast cells are typically not present in early chronic leukemias or mild-to-moderate infections. However, blasts may be observed on the peripheral blood smear in patients with anemia associated with primary BM dysfunction (myelodysplastic syndromes). Blasts are also present in patients with severe infection, stress, or trauma, and in those with chronic myelogenous leukemia (CML) in transformation to acute leukemia. C.C.'s platelet count is also low, which may lead to bleeding or bruising. Collectively, these are presenting signs and symptoms of acute leukemia.

The symptoms C.C. is exhibiting are consistent with either AML or acute lymphocytic leukemia (ALL). However, patients with ALL also commonly present with lymphadenopathy and hepatosplenomegaly, which C.C. does not have. It is important to distinguish between these two disorders because treatment regimens differ greatly. AML is more common in adults than in children. For additional information on ALL, see the section on Acute Lymphoblastic Leukemia of Childhood in Chapter 95, Pediatric Malignancies.

Overview of Treatment

Once the diagnosis of AML is established, induction chemotherapy is given with the goal of rapidly restoring normal BM function. Treatment regimens and outcomes differ between younger and older adults. Although there is no clear dividing line between younger and older adults when dealing with AML, in most studies "older adults" are defined as older than age 60 years.

The objective of induction therapy is to reduce the total body leukemia cell population from ~10^{12} to less than the cytologically detectable level of about 10^{9} cells. It is generally assumed, however,

that a substantial burden of leukemia cells persists undetected (ie, presence of “minimal residual disease” [MRD]), leading to relapse within a few weeks or months if no further therapy was administered. The traditional goal of treatment of AML is to produce and maintain a complete remission. Criteria for this are platelet count >100,000 cells/μL, neutrophil count >1000 cells/μL, and BM specimen with <5% blasts.[10]

The induction regimens for AML commonly are “7 + 3” regimens, which combine a 7-day continuous intravenous (IV) infusion of cytarabine (100 or 200 mg/m^2/day) with a short infusion or bolus of an anthracycline given on days 1 through 3. The most commonly used anthracycline in this regimen is daunorubicin, but idarubicin may be used instead.

Sixty to 80% of adult patients with newly diagnosed AML will attain a CR with intensive induction chemotherapy. However, without additional cytotoxic therapy, virtually all patients will relapse within a median of 4 to 8 months. In contrast, patients who receive postremission therapy may expect 4-year survival rates as high as 40% in young and middle-age adults with good-risk disease.[11] High-dose cytarabine (HiDAC) has been the consolidation chemotherapy of choice for more than a decade for younger patients with good- or intermediate-risk disease. Attempts to improve survival rates attained with HiDAC by substituting other agents with different mechanisms of action have not been successful.[12,13] For patients with an abnormal karyotype or with adverse molecular mutations, consolidation with HiDAC followed by an alloHCT with a suitably matched donor is the treatment of choice whenever possible. For patients older than age 75 years, there is no specific standard of care except to enroll in a clinical trial when available. For the large number of patients who are ages 60 to 75 years, most clinicians will base induction and consolidation therapy recommendations on a patient’s performance status, patient’s wishes, and prognostic factors such as cytogenetics and mutation analysis.[14]

Twenty to 30% of young adult patients and 50% of older adult patients with newly diagnosed AML will fail to attain a CR with intensive induction chemotherapy as a result of drug resistance or

death. In addition, a large percentage of patients who initially attain a CR will relapse. The therapy that provides the best chance to cure a patient with relapsed or refractory AML is an alloHCT. The best outcomes appear to be with a myeloablative preparative regimen administered after attaining a CR. However, some patients may be cured with myeloablative HCT even without attaining a CR although their chance of long-term survival is reduced. Nonmyeloablative preparative regimens are considered for patients who are not candidates for myeloablative HCT but have attained a CR.[15] See Chapter 101, Hematopoietic Stem Cell Transplantation, for a complete discussion of HCT for leukemia. Refer to the following online reference for more details about the treatment and prognosis of AML: http://www.cancer.gov/cancertopics/pdq/treatment/adultAML/healthprofessional/page4.

Treatment

GOAL OF THERAPY

Case 96-1, Question 2: C.C.'s karyotype and genetic analyses findings returned as normal and positive for FMS-like tyrosine kinase (TK) 3 internal tandem duplication allelic ratio >0.5 (FLT3-ITD^{high}), respectively. What is the goal of treatment and what type of therapy is indicated for C.C. at this time?

The leukemic cells populating C.C.'s blood are abnormal and incapable of fighting infection. Their rapid proliferation is suppressing red blood cell and megakaryocyte production in the BM. C.C. is at substantial risk for life-threatening infections and bleeding complications. The goal of the initial chemotherapy is to clear the BM and peripheral blood of all blast cells in the hope that normal blood cell components can regenerate. The karyotype and genetic analyses can be very helpful to determine which treatment regimen will provide the highest likelihood for response. Although this information is very helpful, results may be delayed and not

necessarily available for all patients before they start treatment. The molecular analysis guides the decision for therapy and these findings in combination with other prognostic features, as discussed previously, will influence postremission therapy recommendations. In this case, C.C. will start cytarabine 200 mg/m^2 continuous infusion for 7 days with daunorubicin 60 mg/m^2 IV for 3 days and oral midostaurin 50 mg every 12 hours on days 8 to 21. Alternatively, if C.C. had not had any genetic alterations, a therapy regimen that included gemtuzumab ozogamicin could be utilized because his AML is positive for CD33.

INDUCTION THERAPY

Standard induction chemotherapy for AML includes an anthracycline (either daunorubicin or idarubicin) and cytarabine, an antimetabolite. One commonly used regimen includes idarubicin 12 mg/m^2/day on days 1 to 3 as an IV bolus injection, plus cytarabine 100 mg/m^2/day as a continuous IV infusion on days 1 to 7.[16–19] This combination (7 + 3) is one of the most effective chemotherapy regimens used to treat adult AML, with CR rates of 60% to 80%. Continuous infusions of cytarabine are preferred because these regimens produce higher response rates than do bolus injections during induction therapy.[17]

If a patient presents with a very high WBC count, he or she may experience complications associated with hyperviscosity of the blood (eg, ringing ears, stroke, blindness, or headache as a result of impaired oxygen delivery to the central nervous system [CNS], pulmonary infarction). Because it may take several days for cytarabine and idarubicin to substantially decrease the WBC count, the patient may receive hydroxyurea 2 to 4 g orally or undergo leukapheresis to rapidly reduce the WBC count. Leukapheresis is not routinely done unless the patient is experiencing symptoms of hyperviscosity or has a WBC ≥100,000 cells/μL on diagnosis. Early mortality was not reduced by leukapheresis, so it is not recommended unless combined with another agent.[20]

Because C.C.'s initial WBC was 160,000 cells/μL, leukapheresis was initiated together with concomitant hydroxyurea 2 g twice daily.

Approximately 12 hours after initiating leukapheresis, C.C.'s WBC had decreased to 85,000 cells/μL and he was stable enough to proceed to induction therapy. The leukapheresis and hydroxyurea were subsequently discontinued.

Complications of induction therapy

Tumor Lysis Syndrome

CASE 96-1, QUESTION 3: Twenty-four hours after C.C.'s induction chemotherapy was initiated, the following laboratory values were obtained:

WBC count, 72,000 cells/μL
K, 5.4 mEq/L
Phosphorus, 6.2 mg/dL
Uric acid, 9.6 mg/dL
Calcium, 6.1 mg/dL
Creatinine, 1.7 mg/dL

Why have these laboratory values changed so suddenly? Could this have been minimized or prevented? How should these metabolic disturbances be managed?

C.C. presented with a very high number of peripheral blood blasts. On administration of chemotherapy, patients with a hypercellular BM and high number of blast cells can have a rapid lysis of the blast cells and the release of cellular contents. This can result in tumor lysis syndrome (TLS), which is associated with metabolic abnormalities such as hyperuricemia, hyperphosphatemia, hypocalcemia, and uremia.[21,22] These disturbances may lead to arrhythmias and acute renal failure. In most cases, TLS occurs 12 to 24 hours after chemotherapy is initiated. TLS may occur after therapy for other malignancies, particularly in those with a high tumor burden, such as high-grade lymphomas and ALL; it rarely occurs after therapy for solid tumors.

Patients should receive IV hydration (3–4 L/day) beginning 24 to 48 hours before chemotherapy to maintain renal perfusion, optimize the solubility of tumor lysis products, and compensate for fluid losses

caused by fever or vomiting. Goal urine output is at least 100 mL/hour.

Allopurinol, a xanthine oxidase inhibitor that blocks the production of uric acid, should be started before chemotherapy to prevent or minimize the complications of TLS. The recommended adult dosage is 300 to 600 mg/day.[21] C.C.'s serum uric acid and electrolytes should be monitored at least two to three times a day for 24 to 48 hours after initiating chemotherapy. If severe abnormalities occur, more aggressive measures should be initiated. Allopurinol may be discontinued if the serum uric acid is within normal limits, the LDH has normalized, and the WBC count is low. Febuxostat, which is a selective xanthine oxidase inhibitor and has shown noninferiority to allopurinol in this setting, could be used as an alternative but is less frequently utilized because of cost. Rasburicase, a recombinant urate oxidase product, can also be used as prophylaxis in patients who are at high risk for developing TLS or for the treatment of patients who present with or develop TLS. Rasburicase acts as a catalyst in the enzymatic oxidation of uric acid to allantoin, which is 5 to 10 times more soluble than is uric acid and undergoes rapid renal excretion. The recommended dose of rasburicase for both prevention and treatment of TLS is 0.2 mg/kg/dose IV. Rasburicase results in a rapid reduction in serum uric acid (within 4 hours of administration) and is generally well tolerated. In many adult centers, doses of 3 or 6 mg are commonly used. Although rasburicase has demonstrated excellent efficacy and tolerability, its optimal role in the prevention and management of hyperuricemia in adults remains to be defined because of its high cost and lack of a randomized trial comparing its effect with other interventions.

Although C.C.'s serum potassium was low on admission, it has increased significantly as a result of TLS. For this reason, replacement potassium therapy by any method is not recommended before chemotherapy in patients in whom TLS is highly likely. In extreme circumstances, dialysis may be required to correct severe metabolic and electrolyte disturbances associated with TLS. C.C.'s kidneys continued to function throughout. Even though C.C.'s creatinine was above the normal range, his urine output did not

decline substantially, and he was able to proceed without further intervention.

Myelosuppression

Case 96-1, Question 4: C.C. received allopurinol therapy and aggressive hydration throughout his induction chemotherapy. The metabolic abnormalities gradually resolved as his WBC count declined and tumor lysis diminished. What other complications may occur during induction therapy, and can they be treated?

Patients receiving cytarabine and idarubicin induction therapy develop profound anemia, granulocytopenia (eg, WBC count >100 cells/μL), and thrombocytopenia (>20,000 platelets/μL) shortly after therapy is initiated, which usually persist for ~21 to 28 days. In addition, all infectious complications must be considered life-threatening in severely immunocompromised patients such as C.C.

Severe thrombocytopenia may result in bleeding episodes that range in severity from oozing gums to massive hemorrhage. Serious bleeding complications can usually be avoided if patients receive platelet transfusions when their platelet counts decrease to <10,000 cells/μL or when patients experience bleeding.

Other common drug-induced complications that may occur during induction therapy include nausea and vomiting, mucositis, fever, and skin rash (see Chapter 22, Nausea and Vomiting, Chapter 55, Pain and Its Management, and Chapter 94, Adverse Effects of Chemotherapy, Immunotherapy, and Targeted Agents, for additional information and their management).

Postremission Therapy

Case 96-1, Question 5: After completion of his induction chemotherapy, C.C.'s WBC count fell to <100 cells/μL and his platelet count fell to 5000 cells/μL. He received platelet transfusions approximately every 2 to 3 days to prevent bleeding complications. On day 9, he developed a fever of 101.84 °F (38.8 °C). He was started immediately on empiric, broad-spectrum antibiotic therapy for

fever and neutropenia, and it subsequently resolved. On day 29, his WBC count was 5600 cells/μL with a normal differential, and his platelet count was 168,000 cells/μL. He received packed red blood cell transfusions on two separate occasions when his Hgb fell to <7 mg/dL. A repeat BM aspirate showed no evidence of persistent leukemia, MRD testing[23,24] showed low molecular persistence of disease, and C.C. was told that his leukemia was in remission. Nevertheless, his hematologist recommended additional chemotherapy, and C.C. questions why this is necessary. Is postremission therapy necessary, and if so, what therapeutic options are available to C.C.?

RATIONALE

Although >60% of patients treated for AML achieve CR after induction therapy, DFS at 3 years is 46% for patients with good-risk AML, 17% for intermediate-risk, and only 2% for patients with poor-risk AML.[16] Short remissions have been attributed to proliferation of clinically undetectable leukemic cells. Thus, the rationale for administering chemotherapy after remission is to eradicate these residual cells.

In adult AML, postremission therapy (also referred to as consolidation therapy) includes three to four cycles of chemotherapy. Clinical trials have shown that high-dose postremission therapy results in a higher percentage (30%–40%) of long-term (>2–5 years) disease-free survivors than either no or low-dose postremission chemotherapy in patients generally younger than age 60 years.[17] Postremission therapy regimens usually include HiDAC alone or in combination with one or more agents such as an anthracycline or etoposide. Patients ages 60 years and older or those with comorbid disease may not be able to tolerate this intensive postremission therapy. In these circumstances, the risk of life-threatening toxicity may outweigh the potential benefits of high-intensity postremission chemotherapy, but low-intensity therapy could be an alternative. AlloHCT has also been studied in the postremission treatment of AML and is addressed in Chapter 101, Hematopoietic Stem Cell Transplantation.

In conclusion, C.C. should receive consolidation therapy after HiDAC induction with midostaurin because this has been shown to give him the best chance of long-term survival. In addition, because

C.C. was diagnosed with poor-risk disease, he will be followed up closely with at least bimonthly CBCs and a BM biopsy at least every year for 5 years after consolidation. This close follow-up is vital for catching relapse as early as possible with the intent of going immediately to an alloHCT and minimizing additional reinduction therapy if relapse occurs.

Tretinoin and arsenic trioxide for acute promyelocytic leukemia

CASE 96-1, QUESTION 6: Would induction therapy for other subtypes of AML differ from that described previously?

Induction therapy with 7 + 3 is standard for all types of AML, with one exception: APL. APL is uniquely characterized by the t(15;17) translocation that fuses the *PML* gene on chromosome 15 to the retinoic acid receptor-alpha (*RAR*-α) gene on chromosome 17. In clinical trials, all-trans retinoic acid, also referred to as ATRA or tretinoin, has induced complete remission in ~90% of patients with APL. Serial BM aspirations after initiation of ATRA therapy demonstrate progressive differentiation without hypoplasia. Unfortunately, ATRA typically induces brief remissions, but combining ATRA with other agents improves outcomes.[17,25,26] Current evidence supports the use of concurrent ATRA with arsenic trioxide or an anthracycline for induction in the treatment of low-risk APL. For high-risk APL, combinations of ATRA, arsenic, and conventional chemotherapy is the standard of care. In addition, consolidation postremission therapy should include at least four cycles of ATRA and arsenic and an anthracycline-based regimen. Maintenance therapy with intermittent tretinoin has been shown to decrease the relapse rate.

ATRA therapy, although avoiding life-threatening myelosuppression, can produce significant toxicities, including the differentiation syndrome (formerly called retinoic acid syndrome), which manifests as fever, weight gain, respiratory distress, lung infiltrates, pleural or pericardial effusion, hypotension, and acute

renal failure. If this syndrome develops, corticosteroid therapy (dexamethasone 10 mg twice a day for 3 to 5 days with a taper over 2 weeks) should be initiated.[27] ATRA also causes dryness of the lining of the mouth, rectum, and skin; hair loss; skin rash; blepharoconjunctivitis; corneal erosions; muscle weakness; nail changes; depression; elevated liver enzymes; and high cholesterol.[28] Despite the risk of serious complications and death during induction therapy, the long-term disease-free survival (DFS) rate of patients with APL is superior compared with other AML subtypes. Approximately 90% of patients who receive tretinoin-based induction and maintenance therapy are alive 3 to 5 years after diagnosis.[29]

ACUTE MYELOID LEUKEMIA IN THE ELDERLY

CASE 96-1, QUESTION 7: Would recommendations for induction and postremission therapy differ if C.C. were elderly (age 60 years and older)?

As mentioned, the incidence of AML increases with advancing age. The prognosis of patients with AML is also directly related to age. Older patients are generally less able to tolerate intensive induction and postremission chemotherapy. Older patients often have comorbid medical conditions and a poor performance status, which are directly associated with worse outcomes with conventional AML therapy.[14]

Since 2015, several new options have become available to this age group and have significantly expanded the options available to elderly patients with AML. For patients whose disease has no actionable alterations, less-intensive chemotherapy options such as azacitidine, decitabine, or low-dose cytarabine may be used with or without venetoclax, or, as single agents, glasdegib or gemtuzumab ozogamicin could be used.[30–32] For AML cases that are found to have actionable alterations, including *IDH1*, *IDH2*, and *FLT3* mutations, targeted therapy can be utilized as single agents or combined with less-intensive chemotherapy.[2,14,17,33] Previously, any single-institution or cooperative group study excluded elderly

patients with AML or treated them on a separate, less-intensive protocol. Elderly patients are often judged to be poor-risk candidates for intensive chemotherapy without an objective review of available criteria. Because the median age of patients with AML and myelodysplastic syndrome is 70 years, the results of regimens studied in younger patients may not be applicable to the elderly. Some hematologists believe that it is most appropriate to offer older patients supportive care only, low-intensity therapy, or investigational treatment. Others believe that moderately intensive chemotherapy is beneficial in some candidates. However, most physicians feel uncomfortable offering intensive chemotherapy to elderly patients because of the high risk of induction mortality.

Patients who respond to induction therapy will typically continue on the same low-intensity regimen they received as induction therapy for postremission therapy.[2,14,17] AlloHCT could also be considered for fit patients 60 years of age or older who achieve remission after induction therapy.

Refractory or Resistant Acute Myeloid Leukemia

CASE 96-2

Question 1: F.T., a 55-year-old male, is ~40 days after induction therapy with 7 + 3. Initially, his counts recovered on day 25, and a BM biopsy result on day 28 revealed <5% blasts; therefore, he was in remission. Thereafter, a recent CBC showed a significant drop in his platelet count from 150,000 cells/μL on day 30 to 90,000 cells/μL 10 days later. A subsequent BM biopsy result reveals 60% blasts, confirming the diagnosis of relapsed AML.

What are the treatment options for F.T. at this time?

In younger patients, failure to achieve remission or disease relapse remains the major cause of treatment failure. This reflects both the failure of current salvage regimens and the absence of effective strategies to secure long-term DFS in those patients who achieve a second hematologic remission. A wide range of salvage options have been studied, but with <50% of patients achieving a

second remission and median survival figures ranging from 3 to 12 months, there remains considerable room for improvement.[34]

The treatment of relapse in a patient younger than age 75 years with a good performance status generally comprises one of several salvage options, including targeted therapies, chemotherapy regimens (aggressive or less aggressive), and clinical trials.[17,35] Commonly used aggressive chemotherapy regimens in the relapsed/refractory setting include clofarabine, intermediate-dose cytarabine to HiDAC, or combination regimens such as fludarabine, cytarabine, and filgrastim,[36] or cladribine, cytarabine, and filgrastim,[37] followed by alloHCT.

CHRONIC MYELOGENOUS LEUKEMIA

Epidemiology and Pathophysiology

Chronic myeloid leukemia (CML) is a myeloproliferative disorder characterized by unregulated stem cell proliferation in the BM and an increase in mature granulocytes in the peripheral blood. The disease is relatively rare, representing only 0.5% of all cancer cases and 15% of new leukemia cases.[38–40] The median age of diagnosis is 65 years, and the current estimated 10-year survival rate is 80% to 90%.[38,40]

Clinical Presentation and Diagnosis

Approximately 50% of patients are asymptomatic at presentation, with the most common physical finding of splenomegaly occurring in 50% to 60% of patients.[40] Additional symptoms may include fatigue, abdominal fullness, fever, anorexia, and weight loss. For many patients, the suspicion of CML is based solely on an abnormal CBC with a confirmatory BM biopsy result revealing the hallmark of CML, the Ph chromosome, which is a translocation of chromosomes 9 and 22: t(9;22)(q34;q11).[41] This fusion gene creates a new protein (BCR-

ABL) that has unregulated TK activity, a malignant transformation that leads to abnormal cell cycling, inhibition of apoptosis, and increased proliferation of cells.[40] The natural history of CML can be divided into three distinct phases: chronic phase, accelerated phase, and blast phase. The vast majority (90%–95%) of patients are diagnosed in the chronic phase, which is the earliest phase of the disease.[40]

Treatment

Oral small-molecule tyrosine kinase inhibitor (TKI) therapy revolutionized CML treatment, improving the 10-year survival rate from 20% a few decades ago to 80% to 90% in the present day.[40] Hematopoietic stem cell transplant (HCT) remains the only curative therapy for CML. However, owing to its substantial risks of morbidity and mortality, TKIs are almost always utilized as first-line treatment. The indication for HCT has remained for patients in accelerated or blast phase, those who fail TKI therapies, or for patients who develop certain genetic mutations.[42] Although the exact timing and utility of HCT remains controversial, patient outcomes are dependent on disease stage, with patients having improved 4-year DFS rates if transplanted in the chronic phase (80%) as compared to the accelerated (30%–40%) or blast phase.[43] Additional information regarding HCT for CML can be found in Chapter 101, Hematopoietic Stem Cell Transplantation.

The primary goal of the TKI therapy is to prevent progression from chronic phase to accelerated or blast phase while achieving response to therapy within 12 months of initiation.[41] Assessment of response to TKIs is based on hematologic, cytogenetic, and molecular responses (**Table 96-2**). Hematologic response is defined by normalization of peripheral blood counts and resolution of symptoms. Cytogenetic response is determined by the percentage of Ph-positive chromosomes within the BM cells in metaphase; this was the most widely used monitoring technique until the advent of molecular monitoring with quantitative polymerase chain reaction

(qPCR) assays that detect BCR-ABL messenger ribonucleic acid (mRNA) transcripts in the blood. qPCR is utilized at 3-month intervals to monitor BCR-ABL transcript levels for the failure of treatment or recurrence of disease.[40]

Table 96-2
Definition of Hematologic, Cytogenetic, and Molecular Response in Chronic Myelogenous Leukemia

Response Type	Response Criteria
Hematologic	Complete response: Peripheral white blood cell (WBC) count <10 × 10^9/L Platelet count <450 × 10^9/L Immature cells absent in peripheral blood Signs or symptoms of disease (such as palpable splenomegaly) absent
Cytogenetic	Complete cytogenetic response (CCyR): 0% Ph-positive metaphase cells Major cytogenetic response (MCyR): 0%–35% Ph-positive metaphase cells Partial cytogenetic response (PCyR): 1%–35% Ph-positive metaphase cells Minor cytogenetic response: >35%–65% Ph-positive metaphase cells
Molecular	Early molecular response (EMR): BCR-ABL1 mRNA ≤10% at 3 and 6 months Major molecular response (MMR): BCR-ABL1 mRNA ≤0.1% or ≥3-log reduction from the standardized baseline, if quantitative polymerase chain reaction (qPCR) is not available Deep molecular response (DMR): ≥4-log reduction in BCR-ABL1 mRNA if the assay's level of sensitivity is ≤0.01%, or ≥4.5-log reduction in BCR-ABL1 mRNA if the assay's level of sensitivity is ≤0.0032%

Signs and Symptoms

CASE 96-3

QUESTION 1: S.E., a 66-year-old female, recently had a routine CBC drawn during her annual wellness visit. Her CBC showed a WBC count of 133 × 10^9/L with 15% basophils, and a platelet count of 300 × 10^9/L. The only pertinent physical finding was splenomegaly. On further workup, a BM aspirate revealed a hypercellular marrow with <10% blasts. Cytogenetic analysis confirmed a diagnosis of Ph-positive CML in the chronic phase. S.E. was asymptomatic at diagnosis even though her WBC count was very high.

What are the possible clinical consequences of this abnormally high value?

S.E.'s labs indicate hyperleukocytosis, which is a WBC count >100 × 10^9/L. Leukostasis is present in 5% to 20% of patients with untreated, newly diagnosed CML.[20] The abundance of leukemic blasts in the blood may increase blood viscosity, affecting the brain and lungs, manifesting as cerebrovascular accidents, headaches, dizziness, tinnitus, and dyspnea.[20] Interestingly, S.E. is asymptomatic except for splenomegaly, which occurs in 50% of patients with newly diagnosed CML.[40] The presence of Ph-positive chromosomes within S.E.'s BM establishes her CML diagnosis and the percentage of blasts and basophils confirm her phase as chronic using the WHO Criteria for CML Staging (see **Table 96-3**).

Table 96-3
World Health Organization Criteria for Chronic Myeloid Leukemia Staging

Chronic phase	Blasts <10% in peripheral blood and bone marrow
Accelerated phase	Blasts 10%–19% in peripheral blood or nucleated bone marrow cells Persistent or increasing splenomegaly or WBC count (>10 × 10^9/L), unresponsive to therapy Persistent thrombocytopenia (platelets <100 × 10^9/L) unrelated to therapy or persistent thrombocytosis (platelets >1000 × 10^9/L) unresponsive to therapy Peripheral blood basophils >20% Cytogenetic evidence of clonal evolution
Blast phase	Blasts ≥20% of peripheral blood or nucleated bone marrow cells

	Extramedullary blast proliferation Large foci or clusters of blasts in the bone marrow

WBC, white blood cell.

Clinical Course and Prognosis

Case 96-3, Question 2: What is the prognosis for S.E. and others with newly diagnosed CML?

S.E. has been diagnosed with chronic-phase CML, which may range in duration from a few months to many years. Because symptoms can be nonspecific and relatively minor, CML may remain undiagnosed until patients progress into more advanced stages. S.E.'s prognosis is good and her projected 10-year overall survival (OS) is 80% to 90% if treated with a TKI.[40] Carefully selected patients may even discontinue TKI therapy and maintain observation only if they sustain a deep molecular response for several years with TKI treatment.[40]

If S.E.'s leukocytosis progresses despite therapy, an increased number of blasts would appear in the peripheral blood signaling the second phase of the disease, the accelerated phase. The accelerated phase can progress quickly to the blast phase if left untreated. The estimated 4-year OS is 40% to 55% for those patients with accelerated-phase CML who are started on TKI therapy.[40] The blast phase is the final phase of the disease, defined as 20% or more blasts in the peripheral blood or BM. During this phase, CML is indistinguishable from AML with the exception of cytogenetics and is often refractory to conventional induction chemotherapy regimens for AML when treated. The median survival for patients in this phase is ~9 to 12 months, with alloHCT considered as a first-line treatment option.[40]

Treatment

Case 96-3, Question 3: What therapy is appropriate for S.E.'s chronic-phase disease?

With the approval of TKIs, treatment of CML has shifted toward disease management. Because S.E. was asymptomatic upon presentation, she will receive one of the TKIs approved for first-line management of chronic-phase CML.

TYROSINE KINASE INHIBITORS

Imatinib, a first-generation TKI, inhibits BCR-ABL kinase, which prevents phosphorylation of substrates that are involved in regulating the cell cycle.[44] Approval was based on the pivotal IRIS (International Randomized Study of Interferon and STI571) trial, which compared imatinib with the combination of interferon (IFN)-α plus low-dose cytarabine in patients with newly diagnosed CML in chronic phase. A total of 1106 patients were randomized to either imatinib (400 mg orally daily) or IFN-α/cytarabine.[44] All primary and secondary end points of the trial demonstrated superiority of imatinib versus IFN-α/cytarabine. As a result, TKIs became standard-of-care, first-line therapy for patients with newly diagnosed CML in chronic phase. At the 8-year follow-up of the IRIS trial, 55% of the patients were still taking imatinib, and the estimated OS was 85%.[45] The most common toxicities reported with imatinib are edema, nausea, muscle cramps, and rash.

Dasatinib is a second-generation TKI that binds the BCR-ABL protein in the active confirmation, making it 350 times more potent than imatinib.[46] Approval was based on the international DASISION (Dasatinib Versus Imatinib Study in Treatment-Naive CML Patients) trial, which compared dasatinib (100 mg orally daily) with imatinib in 519 patients in chronic phase.[46] The primary objective of CCyR at 12 months and the secondary objective of a MMR by 12 months were statistically superior for dasatinib versus imatinib. Dasatinib demonstrates a similar safety profile compared with imatinib, but with

a higher incidence of pleural effusion, pulmonary hypertension, and platelet inhibition.[47]

Nilotinib is a second-generation TKI that is structurally similar to imatinib but 30 to 50 times more potent as a result of an improved structural fit in the receptor pocket.[48] Approval was based on the international ENESTnd (*E*valuating *N*ilotinib *E*fficacy and *S*afety in clinical *T*rials—newly diagnosed patients) trial, which randomly assigned 846 patients with chronic-phase CML to either imatinib or two different doses of nilotinib (300 or 400 mg orally twice daily). At 12 months, both doses of nilotinib were statistically superior for molecular response and CCyR compared with imatinib.[48] Upon follow-up, molecular remission rates between the nilotinib arms and the imatinib arm increased from 6% to 10% at 1 year to ~21% to 23% by 5 years.[49] Nilotinib has a higher incidence of QTc prolongation, metabolic syndrome, pancreatitis, and ischemic events among the TKIs.[49]

Bosutinib, a second-generation TKI with dual SRc kinase inhibition, was initially investigated as an option for therapy after resistance or intolerance to prior TKIs. In the single-arm Study 200, a total of 118 patients with prior TK therapy exposure received bosutinib (500 mg orally daily), achieving a 4-year OS of 78%.[50,51] Bosutinib is now utilized in the front-line setting. The international BFORE (*B*osutinib trial in *F*irst-line chr*O*nic myelogenous leukemia t*RE*atment) trial compared bosutinib (400 mg orally daily) with imatinib in 536 patients with newly diagnosed CML. At 12 months, the molecular response (47.2% vs 36.9%) and CCyR (77.2% vs 66.4%) were both superior with bosutinib.[52] Gastrointestinal toxicities such as diarrhea, nausea, abdominal pain, and transaminitis are common with bosutinib.

Selection of a first-line agent is based on careful assessment of TKI toxicities, drug–drug interactions, disease risk score, patient comorbidities, compliance, and performance status. Adherence to therapy is of utmost importance because poor adherence is correlated with suboptimal treatment responses.[53] First-line use selection of second-generation TKIs in higher risk patients may result in faster molecular responses, but no difference in OS

(possibly secondary to increased toxicities) over imatinib.[41] Because S.E. presented in chronic-phase CML, initiation of imatinib, dasatinib, nilotinib, or bosutinib is appropriate, and S.E.'s physician chose to start her on imatinib 400 mg once daily.

Relapsed and Refractory Disease

Case 96-3, Question 4: On routine follow-up at 3 months, S.E. is found to have an 11% BCR-ABL transcript level. Her side effects and compliance were evaluated, where she was found to be 90% compliant because of nausea. She was counseled on medication adherence and nausea management, and then reevaluated at 6 months. The BCR-ABL transcript level was measured at 15% and her BM revealed 36% Ph-positive metaphases. Because S.E.'s compliance had improved, the disease appeared to be imatinib resistant. Imatinib was discontinued and dasatinib was initiated at 100 mg once daily. S.E. maintained low BCR-ABL assays until 12 months, when her BCR-ABL transcript level increased to 12%. Cytogenetic analysis revealed that her disease had become resistant to dasatinib. What treatment options are available for S.E. at this time?

Although S.E. has relapsed, she has multiple treatment options: nilotinib, bosutinib, ponatinib, and omacetaxine. Both nilotinib and bosutinib can be used for second-line treatment, whereas ponatinib and omacetaxine are generally reserved for patients with resistance or intolerance to at least two prior TKI therapies.

Ponatinib is a second-generation TKI that is 500 times more potent than is imatinib, usually reserved for patients who have exhausted other TKI options or who develop a particularly catastrophic gene mutation (T315I, the "gatekeeper" mutation).[41] The PACE (Ponatinib Ph+ ALL and CML Evaluation) trial enrolled 449 patients with heavily pretreated CML; a major cytogenetic response was achieved in 56% of patients in chronic phase, with a CCyR in 46% of patients and a 12-month OS of 94%.[54,55] Ponatinib is associated with arterial occlusions, venous thromboembolism, heart failure, and hepatotoxicity, and thus carries a black box warning for these toxicities.

Omacetaxine is a subcutaneously-delivered protein synthesis inhibitor that can be used in patients in chronic phase who have

failed or were intolerant to at least two TKIs.[41] Of 62 heavily-pretreated patients with chronic-phase CML in the CML 202 Study and 46 patients in the CML 203 Study, the CCyR rates achieved were 16% and 4%, respectively, with median OS of 30 months.[56,57] S.E.'s next treatment would be based on her tolerability of the first two therapies, genetic mutations, concomitant medications, and comorbidities.

LYMPHOMA

Incidence and Epidemiology

The lymphomas represent a dramatically diverse collection of hematologic malignancies originating from lymphoid tissues. The heterogeneity among these lymphoproliferative disorders is manifest by variations in pathophysiologic features, disease course, and therapeutic approach. Disease may present within the lymph nodes or in extranodal sites such as the gastrointestinal tract, skin, BM, sinus, or CNS. Lymphomas are classified as either HL or NHL. The NHLs are further divided into >20 subtypes according to factors such as the cell of origin, histology, and natural history. A review of lymphoma classifications is presented in **Table 96-4**. Refer to Chapter 95, Pediatric Malignancies, for further discussion of pediatric lymphomas.

Table 96-4
Simplified Classification of Lymphomas

	Cell of Origin
Hodgkin Lymphomas	
Classic Hodgkin lymphoma	B cell
Nodular lymphocyte predominant	B cell

EPIDEMIOLOGY, PATHOPHYSIOLOGY, AND ETIOLOGY

The lymphomas impact all age populations, with prevalence differing not only according to disease type but also additional factors such as geographic region, ethnicity, and socioeconomic status.[39,58] Causality is often not established; however, certain viral infections including Epstein–Barr virus and human immunodeficiency virus as well as immunosuppression, autoimmune disease, and family history contribute to an increased risk.[59–63]

CLINICAL PRESENTATION AND DIAGNOSIS

CASE 96-4

QUESTION 1: E.A. is a 39-year-old female with a 2-week history of fevers, lymphadenopathy, malaise, and shortness of breath that was initially treated with antibiotics for suspected pneumonia. Progressive symptoms resulted in a hospital admission where radiologic evaluation revealed diffuse lymph node enlargement.

Are E.A.'s symptoms consistent with aggressive or indolent lymphoma?

E.A.'s presenting symptoms of fevers, lymphadenopathy, and malaise are all generalized signs of lymphoma, with the respiratory symptoms being consistent with pulmonary infiltration of malignant cells. The rapid onset and extensive disease involvement at presentation are suggestive of aggressive lymphoma. A biopsy of an involved node is essential to establish a definitive diagnosis and determine the subtype of lymphoma.

CASE 96-4, QUESTION 2: What diagnostic evaluation is necessary to establish the diagnosis of lymphoma for E.A.?

Suspicion of lymphoma requires a confirmatory biopsy of the lymph node or involved tissues. Morphology, immunophenotyping, flow cytometry, and cytogenetic techniques are utilized to refine the diagnosis. Additional patient assessment should include a complete history and physical examination with a focus on lymph node–bearing areas along with laboratory analysis including CBC, comprehensive metabolic panel, and human immunodeficiency virus serology. Radiologic evaluation includes computed tomography (CT) or positron emission tomography (PET) to evaluate the extent of disease. Staging is typically based on the Lugano classification system.[64] A simplified version of this schema is shown in **Table 96-5**. A BM biopsy or lumbar puncture may be advisable under certain clinical circumstances. Assessment of baseline cardiac and pulmonary function is necessary for all patients expected to be treated with anthracyclines or bleomycin, respectively.

Table 96-5

Simplified Staging of Lymphoma

Stage		Description
Early	I	Disease limited to a single lymph node region
	II	Multiple lymph node regions involved on the same side of the diaphragm
Advanced	III	Lymph node regions involved on both sides of the diaphragm
	IV	Diffuse disease involving one or more extranodal organs

A: absence of any of the B symptoms
B: unexplained fever, drenching night sweats, or unexplained weight loss >10% of body weight during the previous 6 months

Source: Adapted from Cheson BD, Fisher RI, Barrington SF, et al. Recommendations for initial evaluation, staging, and response assessment of Hodgkin and non-Hodgkin lymphoma: the Lugano classification. *J Clin Oncol*. 2014;32:3059–3068.

TREATMENT

Chemotherapy, monoclonal antibodies, small-molecule inhibitors, radiation, HCT, and chimeric antigen receptor (CAR) T-cell therapy are all used in various combinations and sequences in lymphoma therapy. Selection of treatment is guided according to each specific classification of disease. Aggressive lymphomas, such as diffuse large B-cell lymphoma (DLBCL) and HL, are generally treated with intensive combination chemotherapy regimens administered with a curative intent. In contrast, indolent lymphomas such as follicular lymphoma (FL) are essentially incurable and are regularly managed with an approach aimed at reducing disease burden and prolonging survival. Individual patient characteristics, including comorbid conditions and performance status, must be carefully considered to optimize outcomes.

A biopsy of a supraclavicular lymph node confirms the diagnosis of aggressive NHL for E.A.

CASE 96-4, QUESTION 3: What are some important supportive care considerations with lymphoma therapy?

Beyond selecting the optimal chemotherapy regimen, care for E.A. will require proper supportive care focused on addressing both treatment- and disease-related complications. Prophylaxis and treatment of TLS is vital upon therapy initiation, particularly for cases such as this involving aggressive and bulky disease. Adequate antiemetics must accompany all chemotherapy. Although common to virtually all lymphoma therapies, regimens designed for aggressive lymphoma are associated with significant hematologic toxicity and risk of infectious complications. As such, appropriate support with granulocyte colony-stimulating factors, antibiotics, and blood product transfusions is imperative. Although the urgent need for treatment may preclude opportunities, fertility counseling for a patient of childbearing age such as E.A. should be offered. Delayed effects of both chemotherapy and radiation may develop more than a decade after conclusion of therapy and include secondary malignancy, cardiovascular disease, and pulmonary dysfunction. Subsequently, survivorship programs designed to monitor for delayed complications of treatment are increasingly valuable when treating theoretically curative diseases.

Hodgkin Lymphoma

CASE 96-5

QUESTION 1: L.G. is a 26-year-old female with a month-long history of painless swelling around her collarbone and drenching night sweats. She reports increased fatigue and "feeling unwell" over the past 6 months. Radiography revealed a cervical, mediastinal, and inguinal lymph node enlargement. Excisional biopsy of the cervical lymph node revealed nodular sclerosing HL. Because of anemia and thrombocytopenia on presentation, a BM biopsy was performed and the result found to be positive for lymphoma cells. All other laboratory values are normal and she is otherwise in very good health.

What is the goal of therapy for L.G.?

HL, formerly referred to as Hodgkin disease, is a B-cell neoplasm consisting of characteristic Reed–Sternberg cells within an inflammatory background. HL represents ~10% of lymphomas and

accounted for an estimated 8500 new diagnoses in 2020 in the United States.[38,39] Occurrence of HL displays a bimodal age distribution primarily occurring in young adults with a second peak at ~age 65.[65] Although once a uniformly fatal disease, improvements in treatment over the past 50 years represent a remarkable success story because now at least three out of every four new cases can be cured.[66] Given that long-term survival is expected for most patients, delayed consequences of therapy have a heightened importance in management of this disease.[67,68]

HL is categorized as either classic HL or nodular lymphocyte predominant according to the appearance of tumor cells and the composition of the tumor microenvironment.[69] Classic HL is further subdivided, in order of prevalence, as nodular sclerosing, mixed cellularity, lymphocyte rich, and lymphocyte depleted.[70] Nodular lymphocyte-predominant HL accounts for only 5% of all HLs and has a unique immunophenotypic profile and therapeutic approach. The remainder of this section focuses on classic HL.

Prognosis is multifactorial and incorporates systemic symptoms, stage of disease, and the size of the mass. The International Prognostic Score (IPS) for HL describes hypoalbuminemia (albumin <4 g/dL), anemia (Hgb <10.5 g/dL), male gender, age 45 years or older, stage IV disease, leukocytosis (WBC ≥15,000/mm^3), and lymphocytopenia (lymphocyte count <8% of WBC and/or lymphocyte count <600/mm^3) as adverse indicators.[71] The European Organization for the Research and Treatment of Cancer (EORTC) criterion is commonly employed to divide patients into one of three groups—early-stage favorable, early-stage unfavorable, and advanced disease. Early-stage favorable patients have stage I or II disease and have no large mediastinal adenopathy, an erythrocyte sedimentation rate ≤50 mm/hour, three or less involved nodes, and are age younger than 50 years. Patients with stage I or II disease not meeting this criterion are classified as early-stage unfavorable, whereas patients with stage III or IV HL are considered to have advanced disease.

The goal of therapy for L.G. is curative. Although L.G. presents with advance disease, she maintains a favorable long-term

prognosis.

INITIAL THERAPY

CASE 96-5, QUESTION 2: What is appropriate initial therapy for L.G.?

The objective of initial therapy in HL is to maximize the potential for disease eradication while simultaneously limiting the risk of late effects. In modern practice, this is largely achieved by adjusting therapy according to both prognostic factors and response to treatment. Patients with advanced disease at diagnosis and/or residual disease after initiation of treatment generally receive more intensive or longer durations of treatment.

Selection of chemotherapy

The ABVD regimen is the most commonly used initial therapy in modern practice because it displays superior efficacy and reduced incidence both of acute toxicities and long-term complications such as secondary leukemia and sterility when compared to historical alternatives. Although there are exceptions, the majority of patients now begin treatment for HL with two cycles of ABVD followed by restaging with a PET/CT. Depending on both initial staging and degree of disease response, treatment is continued for an additional one to four cycles. Abbreviated treatment courses are reserved for patients with more robust treatment responses and/or more favorable disease characteristics.[72–74] For patients receiving prolonged courses of treatment, the bleomycin may be omitted from ABVD (referred to as the AVD regimen—doxorubicin/vinblastine/dacarbazine).[75] A distinctive feature of ABVD is the general avoidance of dose reductions or delays secondary to leukopenia because of the heightened importance of maintaining dose intensity in this disease.[76,77]

Select patients may benefit from escalating therapy to the BEACOPP (bleomycin/etoposide/doxorubicin/cyclophosphamide/vincristine/proc

arbazine/prednisone) regimen. This intensive combination appears to improve tumor control, although a definitive survival advantage has yet to be elucidated.[78–80] Individuals with advanced disease, four or more adverse IPS factors, and the physical capacity to tolerate the markedly increased toxicity of the combination are likely to derive the greatest potential advantage from this approach. In addition, patients exhibiting limited response to ABVD may experience improved disease response from converting to BEACOPP.[75,81] Another suitable alternative to ABVD is A+AVD (brentuximab vedotin/doxorubicin/vinblastine/dacarbazine). This novel combination, which is identical to ABVD except for the substitution of the CD30 targeting antibody–drug conjugate brentuximab vedotin for bleomycin, is particularly useful in patients in whom bleomycin is contraindicated.[82]

Incorporation of radiation therapy

HL is highly sensitive to radiation therapy. Although treatment with radiation alone is no longer an acceptable approach to treatment owing to substantial long-term toxicity, combined modality therapy—whereby radiotherapy is initiated following a shorter course of chemotherapy—is a reasonable option for patients with early-stage disease.[73,74,83–86] Comparative studies suggest that chemotherapy alone portends a reduced risk of latent adverse events, whereas chemotherapy followed by radiotherapy has a lower rate of disease recurrence. There does not appear to be a difference in OS between these two approaches.[87–89]

L.G. should be treated with two cycles of ABVD followed by restaging with a PET/CT and additional chemotherapy according to response. She would not be eligible for combined modality therapy owing to the fact she has advanced disease. Given the IPS score is <4 and there is no reason to suspect contraindication to bleomycin, an alternative regimen such as BEACOPP or A+AVD is not likely warranted in this situation.

RELAPSED AND REFRACTORY DISEASE

Case 96-5, Question 3: On routine follow-up 9 months after completion of therapy, L.G. is found to have an extensive recurrence of nodal enlargement that is confirmed to be relapsed disease. What are appropriate treatment options for L.G.?

Unlike numerous malignant diseases, patients with HL maintain a reasonable likelihood of attaining cure in the setting of relapsed or refractory disease. Relapses consisting of minimal disease occurring >12 months after documented remission suggest a better prognosis. Salvage chemotherapy alone or with radiation may be sufficient therapy for patients who received abbreviated chemotherapy in the front-line setting.[90,91] Patients with an early or extensive relapse, relapse after a full course of chemotherapy, or primary refractory disease generally require second-line chemotherapy followed by autologous BM transplant. Effective salvage therapies include brentuximab vedotin (if not used in front-line treatment), either alone or in combination with bendamustine, or multiagent regimens such as ESHAP (etoposide/methylprednisolone/cytarabine/cisplatin), DHAP (dexamethasone/cytarabine/cisplatin), and ICE (ifosfamide/carboplatin/etoposide).[92–97] The PD-1 inhibitors pembrolizumab and nivolumab represent an additional treatment option particularly for patients ineligible for or refractory to BM transplant.[98,99] Overall, selection of therapy in the relapsed/refractory setting is highly dependent on individual patient characteristics and provider preference because there is currently no definitive standard of care.

L.G. should likely receive a salvage regimen such as ESHAP followed by autologous stem cell transplant given her early and extensive relapse. The aim of her therapy should remain curative.

A summary of treatment options for HL is presented in **Table 96-6**.

Table 96-6
Summary of Treatment Options in Hodgkin Lymphoma

Treatment	Place in Therapy
ABVD	Preferred initial therapy

Treatment	Place in Therapy
AVD	Alternative initial therapy
BEACOPP	Alternative initial therapy
A+AVD	Alternative initial therapy
Brentuximab vedotin ± bendamustine	Relapsed or refractory disease
ESHAP	Relapsed or refractory disease
ICE	Relapsed or refractory disease
DHAP	Relapsed or refractory disease
Pembrolizumab	Relapsed or refractory disease
Nivolumab	Relapsed or refractory disease

Non–Hodgkin Lymphoma

NHL is a spectrum of lymphoid malignancies distinguished by variations in clinical features and responsiveness to treatment. In the United States in 2020, there were an estimated 77,240 new NHL cases and 19,940 resulting deaths.[38] Although various histopathologic classification schemes for NHL have been developed and modified as the cellular understanding of NHL has improved, NHLs can essentially be classified as either aggressive or indolent. Approximately 90% of all lymphomas arise from B lymphocytes, with the remaining cases developing from T lymphocytes or, rarely, natural killer (NK) cells. DLBCL and FL are the two most frequently occurring subtypes of NHL and, as such, are the focus of this section.

AGGRESSIVE LYMPHOMA

CASE 96-6

QUESTION 1: P.A., a 64-year-old male, presents with swollen lymph nodes and occasional fevers and night sweats during the past month. Physical examination reveals marked cervical, supraclavicular, and inguinal lymphadenopathy. Laboratory values are normal with the exception of a mild anemia and an elevated LDH. Excisional biopsy of a supraclavicular lymph node confirms a

diagnosis of DLBCL. Flow cytometry finding is positive for CD10, CD19, and CD20 surface markers. He does not have any identifiable extranodal disease.

Is P.A.'s disease considered curable?

Aggressive lymphomas include DLBCL and Burkitt lymphoma. Although these diseases are rapidly fatal if untreated and require intensive treatments, the prospect of attaining cure is reasonable for many patients receiving modern therapy.

DLBCL represents about 25% to 30% of all cases of NHL and is the most common type of lymphoma.[70,100,101] Incidence of DLBCL increases with age, with the median age at diagnosis occurring in the sixth decade of life.[102] Anticipated 5-year survival rates range from ~20% to 75% depending on various prognostic indicators. Adverse indicators include age older than 60 years, elevated LDH, multiple extranodal sites, advanced clinical stage, and poor performance status.[103,104] In clinical practice, DLBCL is further divided into various subtypes. The following review is intended to cover general principles and not the nuances of each unique clinical scenario.

Although the potential for relapse is relatively high given his numerous adverse indicators, the goal of therapy for P.A. is nonetheless curative.

Initial therapy for diffuse large B-cell lymphoma

Case 96-6, Question 2: Given this information, what is generally considered the standard of care for P.A.?

A combination of chemotherapy and immunotherapy with or without radiation is the foundation of therapy for DLBCL. The CHOP protocol has been the prevailing chemotherapy backbone in DLBCL for decades owing to its activity, tolerability, and simplicity in comparison with previously utilized regimens.[105] The inclusion of rituximab, a CD20-targeted monoclonal antibody, with CHOP therapy (R-CHOP) increases survival by ~10% to 15% with only a nominal increase in adverse effects.[106–108] Likewise, therapy with rituximab is

integrated into virtually all treatments for DLBCL. For patients with stage I or II disease, a treatment course consists of three to six cycles of R-CHOP followed by involved field radiation.[109,110] If relative contraindications or aversions to radiotherapy are present, adequate results can typically be obtained by omitting radiation and extending chemotherapy duration.

The large size and/or extent of the disease limit the utility of radiation in patients with advanced disease (stage III/IV or bulky tumors). As such, the administration of R-CHOP for a total of six cycles is the predominant practice in this setting. Restaging with a PET/CT is generally completed after two to four cycles of chemotherapy and again at the end of treatment. Patients who do not achieve an adequate response are treated as having relapsed or refractory disease. Chemotherapy with CHOP plus rituximab for six cycles would be ideal for P.A. The addition of radiation treatment is not beneficial in this setting because P.A. has stage III disease.

Unique circumstances in diffuse large B-cell lymphoma

Case 96-6, Question 3: During completion of pretreatment assessment, P.A. is found to have a past medical history significant for cardiac disease. His ejection fraction is revealed to be 35% following an echocardiogram. Does this finding change the therapeutic approach for P.A.? If so, how?

Notwithstanding its proven reliability, therapy with R-CHOP is not applicable to all patients with DLBCL. Anthracyclines such as doxorubicin are a cornerstone of numerous lymphoma regimens. This presents a significant clinical challenge for patients with underlying cardiovascular disease. Replacing the doxorubicin in CHOP with liposomal doxorubicin (R-CDOP—rituximab/cyclophosphamide/liposomal doxorubicin/vincristine/prednisone) or utilizing the EPOCH-R regimen (etoposide/prednisone/vincristine/cyclophosphamide/doxorubicin/rituximab), which employs infusional doxorubicin, are potential

strategies to minimize cardiac effects.[111,112] If the anthracyclines must be avoided entirely, regimens such as R-CEPP (rituximab/cyclophosphamide/etoposide/prednisone/procarbazine), R-CEOP (rituximab/cyclophosphamide/etoposide/vincristine/prednisone), or R-GCVP (rituximab/gemcitabine/cyclophosphamide/vincristine/prednisone) are feasible alternatives.[113–115] Treatment of very frail or elderly patients with DLBCL represents a similar challenge to those with cardiac disease. Maintaining dose intensity is ideal given the curative intent of therapy; however, this is not attainable for all patients and the use of reduced intensity therapy may be required.[116,117]

The presence of c-Myc, BCL-2, and/or BCL-6 is indicative of a poorer prognosis and reduced responsiveness to conventional therapy.[118,119] Treatment of lymphomas with these findings, often referred to as *double-hit* or *triple-hit* lymphomas, with EPOCH-R as opposed to R-CHOP appears to increase response rates with acceptable tolerability.[120,121]

Use of an anthracycline in P.A. may be ill-advised because of his reduced ejection fraction. As such, an alternative such as R-GCVP should be considered rather than R-CHOP.

Treatment of relapsed and refractory disease for diffuse large B-cell lymphoma

Case 96-6, Question 4: Two years after completing therapy, P.A. experiences a relapse of disease. In addition to his lymphoma recurrence, his physical condition has significantly deteriorated since his first therapy because of worsening of comorbid disease unrelated to his cancer. What is the goal of additional therapy for P.A. now that his disease has recurred?

Eligibility for BM transplant is a critical component in decision-making for the management of relapsed or refractory disease. For patients who are eligible for transplant, the aim is curative, with a course of treatment that includes administration of aggressive chemotherapy to induce maximal response followed promptly by

autologous transplant.[122,123] In select circumstances, alloHCT or anti-CD19 CAR T-cell therapy may be utilized. Numerous intensive regimens have been successfully utilized to induce response before autologous transplant including ESHAP, DHAP, and ICE.[124–126] No option has proved superior to another, and all are associated with significant hematologic and nonhematologic toxicity. Although efficacy data are limited, rituximab is frequently included into these salvage regimens.

The approach to patients who are not transplant appropriate or relapse following transplant is largely palliative. Treatment with less-intensive therapies such as gemcitabine plus oxaliplatin (GemOx) or other combinations of conventional antineoplastics are often effective in eliciting a response as a second-line therapy.[127,128] The antibody–drug conjugate polatuzumab vedotin, which binds to CD79b, has been shown to be an effective treatment when combined with BR as a third-line or later option.[129] Other novel therapies/combinations include tafasitamab plus lenalidomide, brentuximab vedotin (for CD30+ disease), and selinexor.[130–132] Low doses of single-agent chemotherapy may be a useful approach to palliate symptoms caused by large masses.

Now at age 66 and in suboptimal physical condition, P.A. is not a likely candidate for aggressive salvage therapy followed by BM transplant. A reduced intensity treatment such as GemOx may be beneficial in controlling disease, although the aim of therapy in this setting would be palliative.

Other aggressive non–Hodgkin lymphoma subtypes

Burkitt lymphoma is a quintessential aggressive malignancy that demonstrates an exceptionally rapid proliferation rate. Urgent therapy is crucial and must be more vigorous than are conventional DLBCL protocols.[133] Active regimens include Hyper-CVAD (cyclophosphamide/vincristine/doxorubicin/dexamethasone alternating with methotrexate/cytarabine), CODOX-M (cyclophosphamide/vincristine/doxorubicin/methotrexate), and EPOCH.[134–136] Although many of these regimens were developed in

the pre-rituximab era, the monoclonal antibody is generally included given the limited impact on toxicity and evidence suggesting improved responses. Burkitt lymphoma has a greater predilection to involve the CNS than do other lymphoid malignancies. Therefore, use of intrathecal chemotherapy and/or incorporation of antineoplastics that readily penetrate the blood–brain barrier, such as high-dose methotrexate or cytarabine, is an imperative component to Burkitt lymphoma treatment.[137] Although treatment-related complications can be severe, durable remission is attained in 60% to 90% of pediatric and young adult cases.[138] This favorable prognosis dissipates when the disease occurs in older populations.[139]

Mantle cell lymphoma harbors the incurable nature of indolent lymphoma while displaying the capability for rapid proliferation of aggressive disease.[140] Therapy for the disease reflects this dual nature because therapy ranges from low-intensity indolent regimens to high-intensity aggressive regimens. Young and medically fit patients are conventionally treated with intensive regimens such as Hyper-CVAD followed by consolidation with autologous BM transplant and maintenance rituximab.[141] Protocols such as BR, R-CHOP, VR-CAP (bortezomib/rituximab/cyclophosphamide/doxorubicin/prednisone), or lenalidomide plus rituximab followed by maintenance rituximab are ideal for initial therapy in elderly patients or those with significant comorbid disease.[142–145] Second-line or salvage treatment options include trial of alternative initial therapy options or various novel therapies such as Bruton TKIs (ibrutinib, acalabrutinib, or zanubrutinib) or the BCL2 inhibitor venetoclax.[146]

A summary of treatment options for aggressive lymphoma is presented in **Table 96-7**.

Table 96-7

Summary of Treatment Options in Aggressive Lymphomas

Treatment	Place in Therapy
Diffuse Large B-Cell Lymphoma	
Zanubrutinib	Relapsed or refractory disease
Venetoclax	Relapsed or refractory disease

INDOLENT LYMPHOMA

FL is the second most common form of NHL and comprises ~70% of all indolent lymphomas.[147] The condition predominantly appears in patients older than 50 years of age although pediatric variants have been described. A reasonable percentage of patients will survive a decade or longer with disease. The Follicular Lymphoma International Prognostic Index (FLIPI) identifies age 60 years or older, elevated LDH, stage III or IV disease, Hgb <12 g/dL, and five or more involved nodes as adverse indicators.[148]

CASE 96-7

QUESTION 1: T.M. is a 61-year-old male in generally good health who is presenting with a 3-month history of painless axillary lymphadenopathy that seems to "come and go." He is otherwise asymptomatic. An excisional biopsy and pathologic examination revealed follicular B-cell lymphoma. A CT scan showed axillary and mediastinal lymphadenopathy. Laboratory values are normal.

When should treatment be initiated for T.M. and what will be the goal of therapy?

In contrast to aggressive lymphomas, indolent varieties are subject to slow growth and typically do not require treatment until the patient is symptomatic.[149] Although numerous effective treatments are available, indolent lymphomas are frequently incurable and prone to recurrent relapses. Treatment is aimed at prolonging survival and palliating symptoms by reducing disease burden until the malignancy either becomes resistant to therapy and/or transforms to a more aggressive lymphoma.[150] A further distinction from aggressive lymphoma therapy, active treatment of FL can be withheld until the development of disease-related symptoms without compromising

outcomes.[149,151] Advantages to the "watchful waiting" approach include minimizing treatment complications, cost avoidance, and theoretically limiting future drug resistance. Localized symptoms due to nodal disease, compromised organ function secondary to lymphoma infiltration, B symptoms, cytopenias from BM involvement, or aggressive proliferation are generally considered indications to initiate therapy.

Because his disease is presently asymptomatic, a "watchful waiting" approach is reasonable for T.M. Once criteria for treatment are met, therapy can be initiated with the goal being to reduce disease-related symptoms and to prolong survival.

Initial therapy

Case 96-7, Question 2: After a year of observation, T.M. now presents multiple enlarged lymph nodes that are causing discomfort and he has been experiencing unintentional weight loss and night sweats. What is the ideal initial therapy for T.M.?

Myriad treatment options are available for FL including conventional antineoplastics, CD20 targeting monoclonal antibodies, and various targeted agents. For a small subset of patients presenting with early disease, treatment may consist of radiation therapy alone—an option that is potentially curative in rare instances.[152–155] Under most circumstances, initial treatment of FL involves a chemotherapy backbone—such as bendamustine, CHOP, or CVP (cyclophosphamide, vincristine, prednisone)—combined with a CD20 targeting monoclonal antibody—such as rituximab or obinutuzumab. Bendamustine, an alkylating agent with additional properties similar to that of purine analogs, appears to not only be more effective than CHOP or CVP but also exhibit an improved safety profile.[144,156] Nonetheless, CHOP and CVP remain potentially useful chemotherapy components of treatment owing to extensive experience.[157,158]

Similar to B-cell–related aggressive NHL, the availability of CD20 targeting monoclonal antibody has dramatically shaped therapy for FL in the modern era.[158,159] Consequently, rituximab or the type II antibody obinutuzumab are given in conjunction with chemotherapy and generally continued as monotherapy in a maintenance or continuation phase following completion of initial therapy.[160–162] Single-agent rituximab elicits significant response rates with minimal toxicity and is an ideal treatment for patients unable to tolerate the rigors of cytotoxic therapy and/or minimal disease burden.[163,164] In select circumstances, initial therapy with lenalidomide plus rituximab or the radiopharmaceutical ibritumomab tiuxetan may be considered.[165,166]

Given that he is now symptomatic, initiation of treatment is necessary for T.M. A combination of bendamustine and obinutuzumab may be ideal as initial therapy for T.M.

Relapsed and refractory disease

Case 96-7, Question 3: Three years after completing initial treatment, T.M. is found to have thrombocytopenia and neutropenia and multiple enlarged lymph nodes that have gradually increased in size over the past several months. What additional treatment options are available for T.M.?

For many patients, a trial of an alternative first-line regimen is effective in the setting of relapsed disease. Occasionally, a rechallenge with a previously administered regimen is reasonable if it induced a durable remission. Small-molecule inhibitors play an emerging role in this stage of FL management. PI3K inhibitors, including copanlisib, duvelisib, and idelalisib, and the EZH2 inhibitor tazemetostat represent additional alternative therapies.[167,168] Options for the very frail or elderly may include chlorambucil, cyclophosphamide, or single-agent rituximab.

Nearly one in three FLs will transform into an aggressive lymphoma at the time of relapse.[169] In the event of aggressive presentation, a repeat biopsy is required to determine conversion to

alternate histology.[170] If transformation is documented, treatment must be intensified to a protocol consistent with aggressive lymphoma therapy and HCT becomes a more important treatment option, particularly for young and medically fit patients.

The features of T.M.'s relapse suggest transformation is unlikely for T.M. As such, an alternative regimen such as R-CVP may be ideal.

A summary of treatment options for FL is presented in **Table 96-8**.

Table 96-8

Summary of Treatment Options in Follicular Lymphoma

Treatment	Place in Therapy
BR	Initial therapy or relapsed/refractory
R-CHOP	Initial therapy or relapsed/refractory
R-CVP	Initial therapy or relapsed/refractory
Bendamustine + obinutuzumab	Initial therapy or relapsed/refractory
CHOP + obinutuzumab	Initial therapy or relapsed/refractory
CVP + obinutuzumab	Initial therapy or relapsed/refractory
Rituximab	Initial therapy or relapsed/refractory
Copanlisib	Relapsed or refractory disease
Duvelisib	Relapsed or refractory disease
Idelalisib	Relapsed or refractory disease
Tazemetostat	Relapsed or refractory disease

CORE PRINCIPLES		CHAPTER CASES
1	Mammography is a common screening modality used in patients with an average risk of developing breast cancer.	**Case 97-1 (Question 1)**
2	Prevention can include both surgery (prophylactic mastectomy ± bilateral oophorectomy) and chemoprevention. Tamoxifen and raloxifene are two agents approved for breast cancer prevention.	**Case 97-1 (Question 2)**
3	Breast cancer is the most common cancer diagnosed in U.S. females. Many risk factors have been associated with the development of breast cancer; however, the two most common risk factors are gender and age.	**Case 97-2 (Question 1) Case 97-3 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
4	A painless mass is a common presenting symptom for patients. To diagnose the disease and determine the histology, a mammogram and a biopsy are performed. Staging is also performed to determine the extent of disease.	**Case 97-3 (Questions 2–4)**
5	Tumor-specific characteristics help guide treatment selection and contribute to prognosis. The most significant factors are hormonal status (estrogen and progesterone receptor status) and human epidermal growth factor receptor 2 (HER2) status.	**Case 97-3 (Question 5)**
6	Local and systemic treatment can include surgery, radiation, hormonal therapy, chemotherapy, biologic, and/or immunotherapy therapy.	**Case 97-3 (Questions 6–9)**
7	Early-stage disease is highly curable. In the adjuvant setting (after surgery), patients can receive hormonal therapy or biologic therapy, depending on tumor-specific factors and may receive chemotherapy, depending on the size of the disease and the presence of positive axillary lymph nodes.	**Case 97-3 (Questions 7–9)**

CORE PRINCIPLES		CHAPTER CASES
8	Adjuvant chemotherapy can include regimens containing anthracyclines, cyclophosphamide, and taxanes. HER2-targeted therapies can be incorporated if the patient has HER2-positive disease.	**Case 97-3 (Questions 6–8)**
9	Metastatic disease is considered incurable. Decisions regarding therapy will depend on the hormonal status of the tumor, toxicities from previous treatment, or other preexisting comorbidities. Therapies could include systemic therapy (hormonal therapy, chemotherapy, biologic, or immunotherapy) or local treatment (radiation therapy or surgery).	**Case 97-4 (Questions 1–5)**

INTRODUCTION

Breast Cancer

INCIDENCE, PREVALENCE, AND EPIDEMIOLOGY

Breast cancer is the most common malignancy in American females and is second to lung cancer in mortality rates. It arises from the tissues of the breast, usually the ducts (tubes that carry milk to the nipple) and lobules (glands that make milk). In 2020, it was estimated that 279,100 individuals would be diagnosed with breast cancer, and ~42,690 are expected to die from their disease. Approximately 2620 cases were estimated to be diagnosed in males, indicating this is not a disease solely of females.[1]

The incidence of breast cancer declined from 1999 through 2004 because of the decreased use of hormone-replacement therapy (HRT). This decline follows the results of the Women's Health Initiative study, which demonstrated an increased risk of breast cancer in those receiving HRT.[2] As other risk factors in females have evolved over time, changes in incidence rates have followed. Decreased incidences in breast cancer in females with increased body mass index have occurred, and incidence rates have increased in females who have fewer births from 1980 to 2011.[2] One in eight females are expected to develop the disease over the course of their lifetime. However, this frequently quoted statistic may overestimate the risk of breast cancer because it is derived from females who live to 110 years of age.[3]

If breast cancer is diagnosed early, it is curable. The likelihood of diagnosing breast cancer is increased by the use of standardized screening methods. Currently, many different guidelines are available for breast cancer screening, including recommendations from the American Cancer Society (ACS), and the U.S. Preventive Services Task Force (USPSTF).

Pathophysiology

The breast itself is composed of many different structures including fat, muscle, ducts, and lobules (**Fig. 97-1**). Lobules arise from glandular tissue that forms into a spoke-like formation to constitute a lobule of two layers of epithelial cells. The ducts connect the milk-secreting lobules to the nipple.[4] A breast cancer is defined by where the tumor cells originate. The two most common histologic types of breast cancer are ductal and lobular carcinoma. Ductal tumors may be classified as either invasive ductal carcinoma (IDC) if it has invaded through the basement membrane of the duct or ductal carcinoma in situ (DCIS) if it has not. Likewise, lobular tumors may be classified similarly (ie, invasive lobular carcinoma [ILC] or lobular carcinoma in situ [LCIS]). Other types of breast cancers include

inflammatory (which will be discussed later in the chapter) and rare histologies such as tubular or medullary carcinomas or sarcomas.

Clinical Presentation and Diagnosis

Most patients will present with early-stage disease, where the 5-year survival rate is ~90%.[5] Many individuals present with a painless lump found upon breast examination (either by themselves or by a clinician) or with a small mass found only on routine mammogram. Patients who present with metastatic disease typically present with symptoms of their disease based on the metastatic site (such as bone pain with bone metastases or shortness of breath with lung metastases).

Treatment will be determined based on the stage of the disease. Staging is completed by evaluating the size of the tumor (either radiographically or from the surgical specimen), the extent of positive lymph nodes (on physical examination and surgical removal through an axillary lymph node dissection or sentinel lymph node dissection), and the extent of disease (through radiologic examinations including computed tomography [CT] scan of the chest, abdomen, and pelvis and a bone scan to identify any metastatic disease).

Overview of Treatment

The treatment of breast cancer includes multiple modalities. Surgery, radiation, hormonal therapy, chemotherapy, biologic, and immunotherapy can all be used in many different combinations based on a patient's specific disease. If therapy is given before

surgery, it is called neoadjuvant therapy, and if treatment is administered after surgery it is termed adjuvant therapy. Early-stage disease may be treated with surgery; other factors will determine whether additional therapy is needed. The staging of a patient's tumor may require radiation and/or chemotherapy, and tumor-specific characteristics decide whether hormonal, biologic therapy, or immunotherapy will be added. In patients with metastatic disease, the goal is palliation of symptoms and improvement in quality of life.

SCREENING

CASE 97-1

Question 1: M.P. is a 42-year-old female with no personal history of breast cancer. She has a cousin who was diagnosed with breast cancer at the age of 65 years. M.P. is in her doctor's office today to discuss routine breast cancer screening.

Based on M.P.'s personal and family history, would M.P. be considered an average-risk or high-risk patient and what modalities of screening are recommended for average-risk and high-risk patients?

The guidelines for cancer screening for breast cancer were last updated in 2015 and led to major changes in the recommended screening modalities and intervals of obtainment for females of average risk of developing breast cancer.[6] For the average-risk patient, screening involves a mammogram and a breast self-examination (BSE; if the female chooses to do so). Although the risk of breast cancer is low in the 20s, BSE allows a female to become more familiar with her body and better able to discern changes as she ages. Clinical breast examinations have long been part of the screening guidelines, but with the new changes in recommendations, this component of screening has been removed because of a lack of benefit of detecting breast cancer in a female with average risk.

Screening mammography has been the gold standard for breast cancer for many decades. Current guidelines state that for a female of average risk, she should have the opportunity to begin annual mammograms between ages 40 and 44 years and then annual

mammograms should commence at age 45 through 54 years. Once a female turns 55 years old, she could transition to biennial screening or have the opportunity to continue annual screening. The guidelines also recommend for females to continue screening mammograms as long as their overall health is good and their life expectancy is 10 or more years.

For many years, there has been controversy regarding the utility of mammography and when screening should begin (age 40 or 50 years). This controversy has stemmed from recommendations by the USPSTF.[7] Their newest recommendations state that the decision to start screening mammograms before age 50 years should be an individual decision. Females may choose to begin biennial screening between ages 40 and 49 years, but that this may lead to more false-positive results and unnecessary biopsies. The guidelines state that the largest benefit for screening mammograms occurs in females ages 50 to 74 years, and there are insufficient data to support the utility of annual mammograms in female age 75 years or older. Although these screening recommendations can be confusing, the controversy that has stemmed from the changes has heightened the awareness to the general public of the importance of breast cancer screening.

M.P. has no first-degree relatives with breast cancer or other family members affected by early breast cancer. M.P. is an average-risk patient, and she should start standard screening modalities and intervals of testing with annual mammograms. She may also decide to do breast self-examinations.

Individuals considered high risk include those that (a) have a known *BRCA* gene mutation, (b) are untested for the *BRCA* gene mutation but have a first-degree relative with a *BRCA* mutation, (c) have a lifetime risk of experiencing breast cancer of ~20% to 25% or more based on risk estimation models, or (d) have a strong family history of breast cancer.[6] Screening with breast magnetic resonance imaging (MRI) is recommended in high-risk individuals. Annual mammography and breast MRIs should be initiated starting at age 30 years in this population. An MRI allows a radiologist to see a contrasted view of the breast and is more sensitive to detecting

breast cancer. In addition, breast tissue in younger patients can be denser because of higher levels of estrogen, making mammography less sensitive.[8]

PREVENTION

Case 97-1, Question 2: M.P. works at her local hospital as a nurse and is volunteering this year at their breast cancer awareness seminar that is offered by her hospital. She was asked to prepare a talk for the event about breast cancer awareness. She wants to discuss breast cancer prevention. What are the common modalities of breast cancer prevention that M.P. should address and what agents are used for breast cancer prevention?

Prevention is key with any cancer. Females who are considered high risk for breast cancer may decide to undergo prophylactic mastectomy with reconstruction as an alternative to living with the prospect that they may develop breast cancer in their life. This modality of prevention is very successful but does not completely eliminate the risk for developing breast cancer.[9] In addition, prophylactic oophorectomy may also be completed to remove the largest source of estrogen in a premenopausal patient. This does not however eliminate the risk completely from developing breast cancer.[10]

Chemoprevention is also another option. Two agents approved for prevention are tamoxifen and raloxifene. Both are selective estrogen receptor modulators (SERMs). The Breast Cancer Prevention Trial (or P1 trial) was conducted in more than 13,000 high-risk females, who were randomly assigned into three groups: age older than 60 years, ages 35 to 59 years with an increased risk of breast cancer based on a score of at least 1.66 as determined by the Gail risk model, or age older than 35 years with a history of LCIS (a risk factor for developing invasive breast cancer).[11] Females received tamoxifen 20 mg daily or placebo for 5 years of therapy. Tamoxifen significantly decreased the risk of developing breast cancer ($P > .00001$). In addition, this study illustrated toxicities associated with tamoxifen therapy, especially in females age older than 50 years. In

those patients, a higher risk of deep vein thrombosis, stroke, pulmonary embolism, and endometrial cancers was identified.[11]

Raloxifene was also approved for chemoprevention in breast cancer. This originated from observations made in osteoporosis studies with raloxifene where patients who had received raloxifene therapy had a decreased risk of breast cancer. With this information, a large randomized chemoprevention trial of more than 19,000 postmenopausal females was conducted evaluating the use of raloxifene 60 mg daily compared to tamoxifen 20 mg daily for 5 years.[12] There was no difference in the number of invasive breast cancers diagnosed in the two treatment arms (relative risk, 1.02; 95% confidence interval, 0.82–1.28). Interestingly, more noninvasive breast cancers were identified in the raloxifene group (80 cases) compared with tamoxifen (57 cases); however, the clinical significance of this difference is unknown. The tamoxifen arm reported more hot flashes and endometrial cancer, and the raloxifene arm demonstrated fewer thromboembolic events and cataracts but more musculoskeletal problems and weight gain. Based on the results of this trial, raloxifene received an indication for chemoprevention in high-risk females. The aromatase inhibitors, exemestane and anastrozole, have been studied in the chemopreventive setting in postmenopausal patients (NCIC CTG MAP III trial and IBIS II trial, respectively). Although both trials demonstrated reductions in breast cancer incidences, neither agent has been compared with tamoxifen or raloxifene and neither are approved for use in this setting.[13–15]

M.P. should include information on prophylactic mastectomy and both tamoxifen (for pre- and postmenopausal patients) and raloxifene (in postmenopausal patients only) in her talk for females with a high risk of breast cancer.

RISK FACTORS

CASE 97-2

QUESTION 1: B.W., a 55-year-old female, is found to have a 2.2-cm mass in the upper, outer quadrant of her left breast during a routine screening mammogram. The rest of her physical examination is unremarkable. All laboratory values, including the complete blood count and liver function tests, are within normal limits. A chest x-ray is negative. B.W. reports that she had her first menstrual cycle at the age 10 years and has had regular periods since that time. She is married but has never been pregnant.

What are B.W.'s risk factors for developing breast cancer?

Many different risk factors have been identified to be associated with the development of breast cancer. However, in >50% of patients, there are no identifiable risk factors beyond increased age and female gender (**Table 97-1**).[16] An individual's risk increases with each decade of life, and the median age of diagnosis is between ages 60 and 65 years. If the patient has had a previous history of breast cancer or atypical hyperplasia from previous breast biopsies, this increases their risk of developing breast cancer.

Table 97-1
Risk Factors for Developing Breast Cancer

Known Risk Factors
Gender: female > male
Personal history of breast cancer
Family history of breast cancer (first-degree relatives)
Benign breast "cancer" (eg, atypical hyperplasia)
Early menarche (age >12 years), late menopause (age >55 years)
Late first pregnancy (age ≥30 years) or no pregnancy
Advancing age
Long-term use of hormone-replacement therapy (estrogen)
Previous chest wall irradiation
Possible Risk Factors
Alcohol
Obesity
High-fat diet

Source: Reprinted with permission from Rojas K, Stuckey A. Breast cancer epidemiology and risk factors. *Clin Obstet Gynecol*. 2016;59(4):651–672.

Breast cancer is a hormonally mediated disease, and many factors are associated with hormonal influences. Early menarche (generally defined as age younger than 12 years) and late menopause (generally defined as age older than 55 years) expose a female to more estrogen throughout her lifetime.[17] Based on the results of the Women's Health Initiative, the use of HRT was shown to increase risk of breast cancer.[18] Nulliparity, or having children after age 30 years, has been associated with an increased risk (RR increased up to 3.5).[16,17] Oral contraceptives have long been thought to increase the risk of breast cancer. Earlier forms of oral contraceptives contained much higher doses of estrogen compared with products today. The dose of estrogens in those products was thought to increase a female's risk of developing breast cancer. However, a meta-analysis demonstrated a minimal difference in risk no matter the dose of estrogen in the oral contraceptives for a healthy female at a low baseline risk.[19] Hereditary breast cancers (one or more first-degree relatives with the disease) only account for ~10% of breast cancer cases; however, these individuals have the highest risk of developing breast cancer.[20]

B.W. has risk factors that increase her risk of developing breast cancer. B.W. started menses early at age 10 years and therefore has been exposed longer to estrogen, and she does not have any children. She is also age 55 years, and the risk of breast cancer increases with each decade of life. Therefore, all of these are considered risk factors for B.W.

INHERITED BREAST CANCER MUTATIONS

CASE 97-3

Question 1: C.D., a 37-year-old female, is found to have a 2.2-cm mass in the outer quadrant of her right breast during a mammogram. All of her laboratory values were normal, and her chest x-ray was negative. Her family history is

significant in that her mother died of breast cancer at the age of 42 years and her 44-year-old sister had a breast tumor removed 5 years ago.

With C.D.'s family history, what genetic testing could be performed for her or for anyone else in her family? If C.D. did not have a family history of breast cancer, what other tests could be conducted to estimate her risk of developing breast cancer?

C.D. has two first-degree relatives with early-age breast cancer. This would indicate a possible inherited genetic mutation. Genetic testing for the presence of *BRCA1* and *BRCA2* mutations should be discussed with C.D. By age 70 years, a person with a BRCA1 mutation has a ~60% risk of developing breast cancer and a 40% risk of developing ovarian cancer.

BRCA2 mutation carriers have a slightly lower risk of breast cancer (~40%) and a lower risk of developing ovarian cancer (~20%).[20,21] One population with a high incidence of *BRCA* mutations is those of Ashkenazi Jewish descent, which 1 in 50 individuals are *BRCA* carriers.[22] C.D. should meet with a genetic counselor to discuss risks and benefits of genetic testing for her and her family members. The results would then play a role in future screening and preventive strategies.

Patients can assess their risk of developing breast cancer by using validated risk tools. One such instrument for average-risk patients is the Gail model, which considers numerous factors such as age at menarche, age of first live birth, presence of atypical hyperplasia, and number of previous breast biopsies. This model is available online (www.cancer.gov/bcrisktool/). Other models that have been validated include BRCAPRO and the Breast Cancer Risk Assessment Tool (for average-risk patients).[23] BRCAPRO is a statistical program that uses information from both affected and unaffected relatives to predict the likelihood of whether a person would have an inherited mutation in *BRCA1* or *BRCA2.*[24] This tool would be used in an individual with a high risk of developing breast cancer. There are numerous resources for patients and family members to help understand their risk of developing breast cancer. Concerned individuals should have a conversation with their

physician regarding their risk of breast cancer and the utility of these risk assessment tools based on their personal and family history.

Clinical Presentation

Case 97-3, Question 2: What are the typical signs and symptoms of breast cancer and does C.D. have any?

Typical presentation involves the identification of a painless lump on clinical examination by a health care professional, by the patient, or by visualization of a painless lump on mammography. Other symptoms are nipple discharge or retraction, or skin changes of the breast.[25] Fewer than 10% of patients will present with metastatic disease. Symptoms upon presentation can reflect their metastatic disease (ie, back pain: bone metastases; headaches/nausea/vomiting: brain metastases; dyspnea: lung metastases; or abdominal pain: liver metastases).[25] C.D. had a painless lump identified on mammogram as her presenting sign.

Diagnosis

Case 97-3, Question 3: After the identification of C.D.'s breast mass on mammogram, what diagnostic procedures should be done to determine C.D.'s type and stage of breast cancer?

Workup for breast cancer includes radiographic examinations, patient history, and a physical examination. If a mass is palpated, a mammogram is completed to identify the abnormality. A breast ultrasound can also be added after the mammogram to differentiate fluid-filled cysts (which are usually benign) versus discreet masses. Once identified, a biopsy would then be performed to diagnose the disease. This is achieved with a core biopsy—the standard method used to obtain a tissue sample. This procedure uses a large-bore needle for tissue collection and allows for distinguishing invasive

versus noninvasive disease. Other methods are available for tissue diagnosis such as fine-needle aspiration and excisional biopsy, but the core biopsy is considered the standard approach.[25]

Full radiologic testing should also be completed including a CT scan of the chest, abdomen, and pelvis, and bone scan to assess for metastatic disease. The most common places for breast cancer to metastasize are the bone, lung, liver, lymph nodes, and the brain.[26] Evaluation for brain metastases would be performed if the patient is experiencing signs and symptoms such as blurry or double vision, uncontrolled nausea/vomiting, headaches, and unsteady gait. These tests are used to determine the extent and stage of the disease and ultimately help determine the prognosis and treatment of the patient. C.D. will need to undergo a biopsy and full staging with a CT scan of the chest, abdomen, and pelvis, and a bone scan.

Types of Breast Cancer and Staging

Case 97-3, Question 4: C.D. had a core biopsy performed that revealed IDC. Other staging tests included a CT scan of the chest, abdomen, and pelvis and a bone scan. All tests were negative. Physical examination revealed ipsilateral lymph node involvement. Mammogram revealed a 2.2-cm mass in the right breast. What are the common types of breast cancer and what stage is C.D.'s breast cancer?

The histology of breast cancer is typically divided into two categories: invasive and noninvasive (in situ) disease. IDC is the most common type found (~75% of cases) and ILC is second (~5%–10%). The noninvasive tumors are less common (DCIS and LCIS; ductal carcinoma in situ and lobular carcinoma in situ, respectively).[25] Other less common histologies include medullary, mucinous, tubular, and papillary. One of the most aggressive forms of breast cancer is inflammatory breast cancer, which is distinctly different from the other types of breast cancer mentioned. Breast cancer can take years to develop into a mass that is identifiable on physical examination or mammogram. In contrast, the onset of

inflammatory breast cancer is sudden and can develop in weeks. Presentation includes a breast that looks “inflamed,” red, and has the look of an orange peel (“peau d’orange”). The diagnosis may be delayed because the skin has the appearance of cellulitis with antibiotics prescribed first; however, the symptoms do not improve with treatment.[27]

Staging is conducted to evaluate the extent of the disease. This is completed to understand a patient’s prognosis and to help to determine the best treatment course. Staging of breast cancer is determined using the TNM (T, tumor size; N, nodal status; M, any site of metastatic disease) classification. This information is determined by both clinical and pathologic examination. In 2010, the breast cancer staging system was updated by the American Joint Commission on Cancer.[28] Stage I disease involves small tumors (>2 cm) with no lymph node involvement and is highly curable (~98% 5-year survival). Stage II includes small tumors with lymph node involvement or larger tumors (>2 cm and ≤5 cm) with no lymph node involvement. Stage III tumors are larger (>5 cm) with lymph node involvement with a 5-year survival of ~80%. Stage IV disease has metastasized to other distant organs and has the poorest prognosis with a 5-year survival of ~26% (**Table 97-2**).[25-26, 28] Most patients will present with stage I or II disease because of routine screening. Based on C.D.’s clinical staging, she is considered to have stage II disease based on the size of her disease and the involvement of ipsilateral lymph nodes.

Table 97-2
American Joint Committee on Cancer Staging for Breast Cancer

Stage	T	N	M
0	Tis	N0	M0
IA–B	T1–T1a	N0–N1mi	M0
IIA–B	T0–T3	N0–N1b	M0
IIIA	T0–T3	N1–N2	M0
IIIB	T4	N0–N2	M0
IIIC	Any T	N3	M0
IV	Any T	Any N	M1

M, metastatic disease; mi, micrometastasis; N, presence of lymph nodes; N0, no lymph node involvement; N1, movable ipsilateral lymph nodes; N2, ipsilateral axillary lymph nodes (fixed or matted), or clinical ipsilateral internal mammary nodes with no axillary lymph node involvement; N3, ipsilateral infraclavicular lymph nodes, clinical ipsilateral internal mammary lymph nodes, clinical axillary lymph nodes, or ipsilateral supraclavicular lymph nodes with or without axillary or internal mammary lymph node involvement; T, tumor size and/or invasion; Tis, carcinoma in situ; T1, ≤2 cm; T2, >2 to 5 cm; T3, >5 cm; T4, any size with skin invasion or direct invasion to the chest wall; T0 and T1 tumors with nodal micrometastasis only are excluded from stage IIA and are classified as stage IB.

Prognostic Factors

Case 97-3, Question 5: Further pathologic analysis of C.D.'s breast tumor reveals estrogen receptor (ER)–positive and progesterone receptor (PR)–positive disease. Human epidermal growth factor receptor (HER2) testing of the tumor was negative. What routine prognostic factors are evaluated in all patients with breast cancer?

In addition to staging, other prognostic factors should be evaluated to help determine a patient's treatment course. Prognostic factors such as the size of the tumor and lymph node status are important. A larger tumor size denotes a poorer prognosis than a smaller tumor

size, and the presence of disease in the lymph nodes leads to a poorer prognosis than lymph node–negative disease. Further, presence of a high number of positive lymph nodes is directly related to a poorer prognosis. Pathologic testing of the breast tumor gives important prognostic factors such as ER and PR and HER2 status.[29] Tumors that are ER- or PR-positive tend to denote a slower-growing, indolent disease and have a more favorable prognosis than ER- and/or PR-negative disease. Approximately two-thirds of patients diagnosed with breast cancer have ER- and/or PR-positive disease. If a patient has ER- and/or PR-positive disease, hormonal therapy is a treatment option. Tumors that are HER2-positive generally denote more aggressive disease. Approximately 25% of breast cancers test positive for HER2 gene amplification. Although this is indicative of a more aggressive disease, it is a positive predictor for response to trastuzumab.[29]

HER2 positivity is determined by two different methods, immunohistochemistry or fluorescence in situ hybridization (FISH). Either method could be used to determine HER2 status. Immunohistochemistry determines the overexpression of the HER2 protein, and results are reported as 1+, 2+, and 3+. Patients with 3+ overexpression are considered positive for HER2 and will respond to trastuzumab therapy or other HER2-targeted therapies. If a patient is determined to have 2+ overexpression (an equivocal test), then further testing would be conducted with FISH. FISH testing evaluates the HER2 gene amplification by denoting a ratio of the number of gene copies of HER2 compared to the control, and only those patients with positive FISH testing will respond to HER2-targeted therapies.[30]

Other pathologic tests are completed such as nuclear grade (which determines the degree of differentiation of the tumor cells) as well as tests to evaluate the growth fraction of the disease (such as S-phase fraction, Ki-67, and mitotic index).[25] Clinicians use all of these factors (positive and negative) to determine a patient's prognosis and treatment course.

Many patients today present with early-stage disease, which is highly curable. Clinicians can use these tests to determine which

patients should receive more or less therapy based on their recurrence score. One such test is the Oncotype DX assay for patients with ER- and/or PR-positive and lymph node–negative and now, lymph node–positive disease and assigns a patient a recurrence score.[31] Based on the score, clinicians and patients can decide the best treatment course such as hormonal therapy alone (for a low recurrence risk score <17) versus the combination of hormonal therapy and chemotherapy (for those patients with a high-risk recurrence score ≥31). This test has led to many patients foregoing the toxic effects of chemotherapy when treatment was not needed. The RxPONDER trial is currently underway to determine the benefit of chemotherapy in those patients with one to three positive lymph nodes with an intermediate recurrence risk score (16–25). Other data have demonstrated the utility of the Oncotype DX recurrence score in those patients with ER-positive, lymph node–positive disease in determining who should or should not receive systemic chemotherapy.[3132]

Treatment

Case 97-3, Question 6: C.D. was diagnosed with a stage II, ER and PR-positive, HER2-negative IDC of the right breast. Her staging workup was negative. Based on this information what would be C.D.'s likely treatment course?

LOCAL TREATMENT (SURGERY AND RADIATION THERAPY)

Surgery is the definitive treatment in early-stage breast cancer. Many years ago, a more radical approach to the surgical removal of breast cancer was used. This approach, called a radical mastectomy, involved the removal of the entire breast, both the major and minor pectoralis muscle, and a full axillary lymph node dissection on the side of the breast cancer. Increased morbidity was associated with this approach such as shoulder dysfunction and a poor cosmetic appearance. Today, a modified radical mastectomy is used that removes the entire breast along with an axillary lymph node

dissection while leaving the pectoralis muscles intact. This approach leads to equivalent survival compared with radical surgery.[33,34] Radiation may be offered in addition to a modified radical mastectomy if the tumor is >5 cm in size, if the patient has greater than four positive lymph nodes, or if positive tissue margins were present after surgery.[34,35] Clinical trials have also evaluated the use or need of adjuvant radiation therapy in those patients age older than 70 years with a low risk of recurrence. Results demonstrated that omission of radiation could offer similar results without placing that patient at higher risk of unnecessary toxicities of adjuvant radiation therapy.[36] These guidelines are widely debated and the subject of numerous studies evaluating patient populations who would benefit from adjuvant radiation therapy.[34–36]

Conservative approaches to surgery, such as lumpectomy, segmental mastectomy, or quadrantectomy, are also available. If a patient has a small tumor and wishes to preserve the breast, this surgical approach could be used; however, not all patients are candidates for this procedure. Those who are not candidates can include those with multicentric disease (numerous tumors throughout the breast), large tumors in relation to the size of the breast, and inflammatory breast cancer.[25] If the decision is to proceed with breast-conserving surgery, the patient must also undergo adjuvant radiation therapy. Because the surgery only removes the primary tumor, the rest of the breast should be treated with radiation therapy to prevent recurrence of disease. Similar survival rates are observed with modified radical mastectomy versus breast-conserving surgery plus radiation therapy.[33–36]

Larger tumors do not preclude a patient from undergoing breast-conservative surgery. However, to be eligible for this surgery, patients would receive neoadjuvant chemotherapy to help shrink the tumor to a size conducive to breast-conserving techniques. Neoadjuvant chemotherapy also allows the oncologist to assess response to treatment while the tumor is still in place and allows the opportunity to discontinue a particular chemotherapy regimen if the patient is not responding. Most patients will respond to

chemotherapy; however, for those who do not, further chemotherapy (with a different regimen) or radiation therapy may be offered.[37,38]

The presence and extent of nodal disease is assessed through an axillary lymph node dissection. This involves the removal of at least 10 lymph nodes on the same side of the primary tumor to assess for the presence of breast cancer. Lymph node dissection may result in lymphedema, thromboembolism, and infection.[39–41] Sentinel lymph node biopsy is one way to avoid the comorbidities associated with the axillary lymph node dissection. In this procedure, a blue dye (labeled with a radiocolloid) is injected around the breast tumor. Time is given for the dye to drain from the tumor to the lymph nodes. The surgeon is able to identify the sentinel nodes because of the presence of radiocolloid and the blue color. The breast (and presumably the cancer) drains first into the sentinel lymph nodes. Only one or two of the sentinel lymph nodes will be removed, reducing the risk of lymphedema, thromboembolism, and infection.[39–42] Many consider this procedure the standard of care for assessment of the axillary lymph nodes.

C.D. could either undergo breast-conserving surgery plus radiation therapy or a modified radical mastectomy, but with C.D.'s family history she may also choose to undergo bilateral mastectomies to prevent the development of contralateral breast cancer.

SYSTEMIC THERAPY (CHEMOTHERAPY, HORMONAL THERAPY, AND BIOLOGIC THERAPY)

Surgery and radiation therapy eradicate most tumor cells; however, microscopic disease is difficult to detect and treat locally. Microscopic cancer deposits can migrate throughout the body and serve as sites for disease recurrence. To diminish the chance of recurrence, systemic adjuvant chemotherapy, hormonal therapy, and/or biologic therapy is given. The determination of which single modality or combination of therapies is based on the patient's prognostic factors: ER/PR status and HER2 positivity. As mentioned earlier, tools such as the Oncotype DX assay can estimate risk recurrence based on

these tumor-specific characteristics and assist in the determination of therapy.

The size of the tumor and other prognostic factors are also evaluated to determine the course of therapy (**Table 97-3**).[43] Patients with small tumors (0.6–1 cm) and negative lymph nodes can be further divided into two groups based on favorable and unfavorable prognostic features. Favorable prognostic features would include hormone-positive disease. These patients can be offered hormonal therapy without chemotherapy. Those individuals with poor prognostic features (tumors with lymphatic invasion, high nuclear grade, hormone receptor-negative, or HER2-positive disease) would be offered chemotherapy with or without trastuzumab and pertuzumab therapy.[25]

Table 97-3

Overview of the Selection of Adjuvant Treatment

	Adjuvant Hormonal Therapy		Adjuvant Chemotherapy[b]
Lymph Node–Negative Disease	**ER/PR (+)**	**ER/PR (−)**	
≤0.5 cm	Yes	No	No
0.6–1 cm[a]	Yes	No	Consider
>1 cm	Yes	No	Yes
Lymph Node–Positive Disease	**ER/PR (+)**	**ER/PR (−)**	
	Yes	No	Yes

[a]Consider Oncotype DX testing: low recurrence score (<26) = adjuvant hormonal therapy; intermediate recurrence score (26–30) = adjuvant hormonal therapy ± chemotherapy; high recurrence score (≥31) = adjuvant hormonal therapy + chemotherapy.

[b]Give trastuzumab ± pertuzumab therapy if the patient is HER2 (+) and no contraindications.

Source: Barnett CM, Boster BL, Michaud LB. Breast cancer. In: DiPiro JT, Talbert RL, Yee GC, Matzke GR, Wells BG, Posey L, eds. *Pharmacotherapy: A*

Pathophysiologic Approach. 10th ed. McGraw-Hill; 2017. Accessed September 23, 2020.

Tumors >1 cm in size are generally offered treatment with systemic chemotherapy. If the patient is ER- and/or PR-positive, they are additionally treated with hormonal therapy after chemotherapy. Biologic therapy with trastuzumab and pertuzumab is added to chemotherapy if the patient has HER2-positive disease and assuming there are no contraindications such as cardiac disease. Patients should be fully informed of the absolute benefit of chemotherapy because in those with early-stage disease the benefit from chemotherapy could be as low as 2% to 3%. The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) conducts an overview analysis every 5 years on the effects of chemotherapy and hormonal therapy in breast cancer randomized trials. In 2005, the 15-year survival updates were published.[44] Although no standard regimen has been identified, combination regimens are superior to single-agent therapy (recurrence rates and mortality for combination chemotherapy, respectively: hazard ratio [HR], 0.77; $P > .00001$ and HR, 0.83; $P > .0001$, respectively; single-agent therapy recurrence rates and mortality: HR, 0.86; $P = .001$ and HR, 0.96; $P = .4$, respectively).[44] Updated meta-analyses have also included the use of taxanes to fixed anthracycline-based regimens. In the previous EBCTCG trial, taxanes were not included in the data analysis. With the incorporation of taxane therapy, breast cancer mortality was reduced: RR (event rate ratio: newer treatment versus control) = 0.86, standard error (SE) = 0.04, $P = .0005$.[45,46] This demonstrated the benefit of adding taxane therapy to standard adjuvant therapy for specific patients.

Looking back at C.D.'s tumor characteristics, she has stage II (2.2 cm with lymph node involvement), ER-positive, PR-positive, and HER2-negative breast cancer. Based on this information, C.D. would be a candidate for surgery and chemotherapy (based on the tumor size and lymph node–positive disease), followed by hormonal therapy because of her ER/PR-positive disease.

ADJUVANT CHEMOTHERAPY

CASE 97-3, QUESTION 7: C.D. underwent a right modified radical mastectomy and axillary lymph node dissection. She had 4 of 15 lymph nodes positive for disease. Her adjuvant treatment will consist of chemotherapy (because of the larger size of the tumor and positive lymph nodes). What are typical adjuvant chemotherapy regimens for the treatment of early-stage breast cancer, and what should C.D. receive?

Many different combination chemotherapy regimens are used in the adjuvant setting (**Table 97-4**). Anthracycline-containing regimens are commonly used. Doxorubicin or epirubicin in combination with an alkylating agent (cyclophosphamide) plus or minus fluorouracil is a typical regimen. Regimens can be administered in a dose-dense (every 2 weeks) manner or conventional every 3-week dosing. In the most recent EBCTCG analysis, anthracycline-based regimens have significantly lower recurrence rates and death compared to traditional cyclophosphamide, methotrexate, and fluorouracil (recurrence rate ratio, 0.89; $P = .001$; and cancer death rate ratio, 0.84; $P > .00001$, respectively).[45] A large pooled analysis demonstrated improved disease-free ($P > .00001$) and overall survival ($P > .0001$) with the addition of a taxane.[44–46] Updated meta-analyses have also included the use of taxanes to fixed anthracycline-based regimens. As discussed earlier, the optimal taxane regimen has yet to be identified, and the full benefit of the utility of taxane therapy in lymph node–negative disease is yet to be determined; however, the benefit is apparent in lymph node–positive disease and taxanes should be incorporated into the treatment regimen of those with lymph node–positive disease.

Table 97-4
Common Neoadjuvant and Adjuvant Chemotherapy Regimens

Regimen
HER2-Negative Disease
Dose dense[a] AC → paclitaxel every 2 weeks

Regimen
HER2-Negative Disease
Dose dense[a] AC → paclitaxel weekly
TC
CMF, classic (oral) or intravenous
TAC
AC every 3 weeks
AC → paclitaxel weekly
AC → docetaxel every 3 weeks
HER2-Positive Disease
AC → paclitaxel + trastuzumab ± pertuzumab
TCH ± pertuzumab
AC → docetaxel + trastuzumab ± pertuzumab
Docetaxel + cyclophosphamide + trastuzumab
Paclitaxel + trastuzumab

A, doxorubicin; C, cyclophosphamide; F, fluorouracil; M, methotrexate; T, docetaxel; TCH, docetaxel, carboplatin, trastuzumab; →, followed by.

[a]Dose dense, given every 2 weeks instead of every 3 weeks. See source document for specific dosing.

Source: Barnett CM, Boster BL, Michaud LB. Breast cancer. In: DiPiro JT, Talbert RL, Yee GC, Matzke GR, Wells BG, Posey L, eds. *Pharmacotherapy: A Pathophysiologic Approach*. 10th ed. McGraw-Hill; 2017. Accessed September 23, 2020.

Congestive heart failure (CHF) is a well-known toxicity associated with anthracycline chemotherapy. If a patient has heart failure or other preexisting cardiac disease, anthracyclines must be used cautiously. To avoid potential toxicity, taxane regimens such as docetaxel and cyclophosphamide have been compared to a standard anthracycline-containing regimens, doxorubicin and cyclophosphamide. After 7 years of follow-up, both disease-free and overall survival were significantly better in the taxane arm compared with the anthracycline arm (81% vs 75%; $P = .033$ and 87% vs 82%; $P = .032$, respectively).[47] Although the results are encouraging, these

data do not have the track record of the anthracycline-containing regimens that are still considered the mainstay of therapy for adjuvant chemotherapy in early-stage breast cancer. Studies are currently underway to identify specific populations that may not respond to anthracycline therapy, thereby avoiding the risk of cardiac toxicity in these individuals.[48] If these specific cases are identified, more non–anthracycline-based chemotherapy regimens will be incorporated into clinical practice. Based on C.D.'s lymph node–positive breast cancer, a typical adjuvant chemotherapy regimen would consist of doxorubicin and cyclophosphamide (AC) given every 3 weeks for four cycles followed by a taxane such as paclitaxel weekly for 12 weeks or a dose-dense approach with AC given every 2 weeks for four doses with growth factor support followed by paclitaxel weekly for 12 weeks (see Table 97-4 for commonly used adjuvant chemotherapy regimens).

Trastuzumab and pertuzumab therapy can be incorporated into a patient's adjuvant chemotherapy regimen if the tumor is HER2-positive. Trastuzumab was first studied in the metastatic setting and demonstrated improved overall survival when added concurrently with chemotherapy.[49] Because of its robust activity in the metastatic setting, it was then studied in early breast cancer to see whether the same benefit could be achieved. Two large trials were conducted concurrently addressing different questions regarding the use of concurrent, sequential, and maintenance trastuzumab.[50,51] Patients received the classic AC regimen for four cycles followed by paclitaxel weekly given either sequentially or concurrently. Trastuzumab therapy was started after the completion of the AC regimen to reduce potential cardiac toxicities associated with doxorubicin and trastuzumab. The results of these trials were combined and published in full. Disease-free and overall survival were significantly improved with the addition of trastuzumab (52% decrease in recurrence rates, $P > .0001$; and 33% reduction in mortality, $P = .015$, respectively).[50,51] Four-year follow-up data continued to demonstrate significant improvements with trastuzumab compared to chemotherapy alone.

The use of maintenance trastuzumab was further studied in the HERA Trial (Herceptin Adjuvant Trial).[52] In that trial, patients were randomly assigned to complete 1 or 2 years of maintenance trastuzumab therapy. Based on these data, trastuzumab was approved for use in early-stage, HER2-positive disease after the completion of AC therapy followed by sequential paclitaxel therapy for 1 year. Pertuzumab, another monoclonal antibody approved after trastuzumab, targets HER2 but in a different manner. It binds to a different region of the extracellular of HER2 and block the dimerization of HER2 with HER3. As with trastuzumab, pertuzumab was first approved in the metastatic setting, but is now approved for use in both the neoadjuvant and adjuvant setting for HER2 positive breast cancers. Based on the results from the APHINITY trial, use of pertuzumab in combination with trastuzumab in the adjuvant setting for a total of 1 year of therapy improved invasive disease-free survival compared to trastuzumab alone (HR = 0.82 [95% CI, 0.67–1.00; *P* = .047]).[53] With these results, the new standard of care is to complete a total of 1 year of adjuvant trastuzumab and pertuzumab if the patient has HER2-positive disease.

There is now an additional caveat to this recommendation. When a patient undergoes surgical resection after receiving chemotherapy and HER2-targeted therapy, the specimen is analyzed to see if there is any residual disease. Practice had traditionally been to continue the HER2 targeted therapy for a total of 1 year. With results of the Katherine trial, this practice has changed.[54] If the patient has residual disease remaining, the patient will now switch to another HER2-targeted therapy, ado-trastuzumab emtansine to complete a total of 1 year of therapy. Per the Katherine trial, invasive disease-free survival was significantly improved with ado-trastuzumab emtansine compared to the trastuzumab group. The risk of recurrence of invasive breast cancer or death was 50% lower (HR = 0.50, 95% CI, 0.39–0.64; *P* < .001).[54] Because C.D. does not have HER2-positive disease, any HER2-targeted therapy would not be used.

CHEMOTHERAPY TOXICITY

Case 97-3, Question 8: C.D. is to undergo four cycles of AC chemotherapy followed by weekly paclitaxel for 12 weeks. What are the common toxicities associated with this treatment course? If the tumor was HER2-positive and C.D. received trastuzumab, what toxicities would be associated with its use?

Doxorubicin is an anthracycline chemotherapy agent. It works through multiple mechanisms, but inhibition of topoisomerase II may be most important.[55] By inhibiting this enzyme, double-strand DNA breaks occur. Common toxicities include myelosuppression, nausea/vomiting, and alopecia. A well-known toxicity of anthracyclines is the risk of cardiomyopathy because of the formation of oxygen free radicals and doxorubicin metal complexes. These toxicities can be acute (with symptoms similar to an arrhythmia or myocardial infarction) or chronic (with a patient demonstrating symptoms of CHF).[55] The risk of cardiotoxicity increases with larger anthracycline cumulative doses.[55–58] With the typical doses of anthracyclines used in the adjuvant setting, a patient will not reach the cumulative doses known to increase the risk of cardiotoxicity. If a patient has underlying cardiac dysfunction, baseline evaluation of ejection fraction through either an echocardiogram or a multigated acquisition scan should be completed.[55–58] Other known risk factors for the development of anthracycline-induced cardiotoxicity include age older than 70 years, hypertension, preexisting coronary artery disease, and previous cardiac irradiation or anthracycline exposure, which may warrant cardiac evaluation.[59–62]

Cyclophosphamide is an alkylating agent that works by forming cross-links in DNA, thus inhibiting DNA synthesis.[55] Common toxicities are nausea/vomiting, myelosuppression, and alopecia. The alkylating agents, although rare, are also associated with a risk of secondary leukemias.[55]

Paclitaxel, a taxane chemotherapy derived from the Pacific yew tree, works by binding to the β-tubulin subunit of microtubules, preventing disassembly and ultimately causing inhibition of mitosis. Common toxicities associated with paclitaxel include nausea/vomiting, myelosuppression, neuropathy, and

hypersensitivity reactions because of the modified polyoxyethylated castor oil (Cremophor EL) solvent in paclitaxel. All patients should be premedicated with dexamethasone and H_1 and H_2 blockers to prevent hypersensitivity.[63]

Trastuzumab is a monoclonal antibody targeted against the extracellular HER2 protein. The classic toxicity associated with trastuzumab is cardiac toxicity but is different from that with anthracyclines. Trastuzumab cardiotoxicity is considered reversible and is believed to be a result of HER2 blockade (HER2 signaling is responsible for cardiomyocyte growth, repair, and survival).[58–62] In those patients who will receive long-term trastuzumab therapy, baseline cardiac function should be evaluated similar to doxorubicin and then periodically with echocardiogram or a multigated acquisition scan during therapy. The same holds true for other HER2-targeted therapy, such as pertuzumab and ado-trastuzumab emtansine.[64] Another common toxicity associated with HER2-targeted therapy is diarrhea.[65] If this is a problem for the patient, many times one agent, such as pertuzumab, is deleted from the treatment regimen. This change in therapy can decrease the diarrhea that the patient experiences and is more tolerable. C.D. does not have a history of cardiac disease, but a baseline cardiac evaluation should still occur before AC therapy. C.D. should be counseled on the common toxicities associated with her chemotherapy, such as myelosuppression, nausea/vomiting, alopecia, neuropathy, cardiomyopathy, hypersensitivity reactions, and diarrhea.

HORMONAL THERAPY

Case 97-3, Question 9: After the completion of her adjuvant chemotherapy, C.D. will receive hormonal therapy because her disease is ER/PR-positive. What are the common adjuvant hormonal regimens used? What regimen would be appropriate for C.D.?

Breast cancer is a hormonally mediated disease, and therapies that alter hormonal levels are an integral component to the treatment plan. This therapy is offered to patients with ER- and/or PR-positive disease. Therapeutic options include SERMs, luteinizing hormone–releasing hormone (LH-RH) agonists, and AIs. Menopausal status of the patient is used to help guide selection of therapy.

Traditionally, tamoxifen has been the gold standard for adjuvant hormonal therapy. Tamoxifen is an SERM, which works by blocking estrogen from binding to the ER. It does not alter estrogen production. Tamoxifen has antiestrogenic activity in the breast, although it has estrogenic effects in other areas such as bone.[66,67] Tamoxifen can be used in both premenopausal and postmenopausal females and is given 20 mg orally daily for 5 years based on the data from the National Surgical Adjuvant Breast and Bowel Project B-14 trial.[68] Tamoxifen should be initiated after chemotherapy because it can antagonize the antitumor activity of chemotherapy if given concurrently.[69] Common toxicities associated with therapy are hot flashes and vaginal discharge. More thrombosis, pulmonary embolisms, and strokes can occur in patients (age older than 50 years) receiving tamoxifen compared to placebo (RR, 1.60, 3.19, 1.59, respectively).[11,12]

Ovarian suppression is an alternative therapy for premenopausal patients because the ovaries are the largest source of estrogen. This is typically achieved through the use of LH-RH agonists. Surgery or radiation can also induce ovarian ablation; however, surgery is irreversible and offers an immediate effect, whereas radiation may offer an incomplete response and slower onset.[70–72] If a female would like to maintain fertility throughout chemotherapy, a thorough discussion with her physician should occur. Studies with the use of LH-RH agents have been tested as a means to preserve fertility but have shown mixed results.[72] Combination data with an LH-RH agonist with tamoxifen have not shown significantly better outcomes than each modality alone.[70–72]

Postmenopausal patients also have the option of AI therapy. Aromatase inhibitors inhibit the production of estrogen by preventing the conversion of androstenedione and testosterone to estrone and

estradiol. There are two classes of agents: nonsteroidal AIs (anastrozole and letrozole) and the steroidal AI, exemestane. These agents are highly selective for the aromatase enzyme and have less toxicity than tamoxifen and other hormonal agents. Aromatase inhibitors should only be used in postmenopausal females.[25] If used in the premenopausal setting, initial surges of estrogen occur because of the body's compensation mechanisms (ie, hypothalamic–pituitary axis) and negative feedback loop. **Table 97-5** provides a list of adjuvant hormonal therapies that can be used.

Table 97-5
Adjuvant Hormonal Therapies

Type	Dose	Toxicities
Nonsteroidal AI		
Anastrozole Letrozole	1 mg daily PO 2.5 mg daily PO	Common toxicities: myalgias/arthralgias, hot flashes, osteoporosis
Steroidal AI		
Exemestane	25 mg daily PO	Common toxicities: myalgias/arthralgias, hot flashes, osteoporosis
SERMs		
Tamoxifen	20 mg daily PO	Common toxicities: hot flashes, vaginal discharge Rare but serious side effects: deep vein thrombosis, pulmonary embolism, abnormal uterine bleeding

Tamoxifen for prevention of breast cancer: report of the National Surgical Adjuvant Breast and Bowel Project P-1 study. *J Natl Cancer Inst*. 1998;90:1371–1388; Goldvaser H, Barnes TA, Šeruga B, et al. Toxicity of extended adjuvant therapy with aromatase inhibitors in early breast cancer: a systematic review and meta-analysis. *J Natl Cancer Inst*. 2018;110(1):31–39.

The optimal hormonal therapy regimen for the adjuvant setting has not been identified. In premenopausal females, the options are 5

years of tamoxifen therapy plus or minus ovarian suppression with an LH-RH agonist. If the patient continues to be premenopausal at the end of 5 years of adjuvant tamoxifen therapy, the patient may consider five additional years of therapy.[73–76] There are conflicting data to support this recommendation. Based on newer data, the American Society of Clinical Oncology published an updated practice guideline for adjuvant hormonal therapy.[77]

If, after 2 to 3 years, the patient becomes postmenopausal, then 2 to 3 years of an AI may be given to complete a total of 5 years of therapy. If the patient is postmenopausal at the beginning of adjuvant hormonal therapy, an option would be to take an AI for 5 years and then assess again for a potential of a total of 10 years of adjuvant aromatase inhibitor. There have been no prospective comparisons of the AIs with each other; therefore, any can be used as first-line treatment.[73–77] Another clinical option is 5 years of tamoxifen, and, if the patient is postmenopausal after the end of 5 years, an additional 5 years of an AI can be given. This was found to be beneficial in an extended study of hormonal therapy (the BIG 1–98 trial). At the 2.4-year follow-up, additional letrozole therapy was associated with a superior 4-year disease-free survival (93% with extended letrozole vs 87% in the tamoxifen arm; $P > .001$).[78] However, in the 8.1-year follow-up data, the additional letrozole therapy did not improve outcomes compared with letrozole monotherapy in terms of disease-free and overall survival.[79] Each individual's length of therapy should be determined based on the patient's risk of recurrence and their ability to tolerate therapy. **Table 97-6** lists adjuvant hormonal therapy options.

Table 97-6
Overview of Adjuvant Hormonal Therapy

Option 1	Option 2	Option 3
Premenopausal at time of therapy initiation (patients can complete 1 of 3 different options)		

Option 1	Option 2	Option 3
Premenopausal at time of therapy initiation (patients can complete 1 of 3 different options)		
Tamoxifen × 5 years ± LH-RH agonist or ovarian ablation	If still premenopausal after 2–3 years of tamoxifen therapy, complete a total of 5 years of tamoxifen.	If still premenopausal after 5 years of tamoxifen, consider an additional 5 years of tamoxifen.
	If postmenopausal after 2–3 years: **A.** Complete 5 years of tamoxifen followed by 5 additional years of an AI *or* **B**. Convert to an AI × 2–3 years for a total of 5 years of hormonal therapy.	If postmenopausal after 5 years of therapy, give AI × 5 additional years.
Postmenopausal at time of therapy initiation (referred to start with an AI if the patient is postmenopausal at the onset of therapy)		
Any AI × 5 years, then an AI for another 5 years to complete a total of 10 years	Tamoxifen × 2–3 years, then an AI to complete a total of 5 years	Tamoxifen × 4–6 years, then an AI for 5 additional years

AI, aromatase inhibitor; LH-RH, luteinizing hormone–releasing hormone.

Customizing local and systemic therapies for women with early breast cancer: the St. Gallen International Consensus Guidelines for treatment of early breast cancer 2021. *Ann Oncol*. 2021;32(10):1216–1235; Goldvaser H, AlGorashi I, Ribnikar D, et al. Efficacy of extended adjuvant therapy with aromatase inhibitors in early breast cancer among common clinicopathologically-defined subgroups: a systematic review and meta-analysis. *Cancer Treat Rev*. 2017;60:53–59.

C.D. is premenopausal, so she would start with tamoxifen therapy. If after 2 to 3 years of therapy, C.D. becomes postmenopausal, she could continue the tamoxifen for a total of 5 years or convert to an AI to complete a total of 5 years of therapy then continuing the AI for an additional 5 years. Because of her age, she will likely continue to be premenopausal after chemotherapy and be maintained on tamoxifen for 5 years. If she remains premenopausal, she should have a discussion with her physician on the merits of continuing tamoxifen

for a total of 10 years. If she completes 5 years of tamoxifen therapy and is postmenopausal at that time, then extended use of an AI for an additional 5 years would be recommended. At this time, ovarian suppression with an LH-RH agonist could also be added because she is premenopausal to chemically suppress her ovarian function.

METASTATIC BREAST CANCER

Treatment—Endocrine Therapy

CASE 97-4

QUESTION 1: T.R. is a 65-year-old, postmenopausal female diagnosed with breast cancer at age 48 years. At the time of diagnosis, she was premenopausal. She underwent surgery with a modified radical mastectomy and was found to have a 1.5-cm IDC of the right breast. She had 2 of 10 lymph nodes positive. Her breast cancer was ER-positive, PR-positive, and HER2-negative. T.R. went on to complete adjuvant chemotherapy with AC therapy for four cycles followed by weekly paclitaxel for 12 weeks. After completion of her chemotherapy, she received 5 years of tamoxifen therapy. Ten years after completing her therapy, she experiences pain in her right arm and rib cage. A bone scan revealed metastatic breast cancer.

What would be an appropriate treatment regimen for T.R. at this time?

Early-stage breast cancer is curable. However, if a patient develops metastatic disease, the goal of treatment shifts from cure to palliation and stabilization of disease. Treatment is offered to improve quality of life and alleviate symptoms from treatment or disease. The mean survival time after diagnosis of metastatic disease is ~2 to 4 years; however, this can range from months to many years depending on the site of the metastases.[80,81] The choice of therapy is based on the site of disease and other factors that help guide therapy such as ER and PR status. Endocrine therapy is more likely to be effective in patients with bone-only disease, whereas chemotherapy may be used when there is visceral disease (ie, liver or lung). Patients with organ involvement tend to have more rapidly

growing disease that generally requires therapy with a quicker onset of action such as chemotherapy.[25] In addition to systemic therapy (chemotherapy, hormonal therapy, and/or biologic therapy), the clinician needs to determine whether local therapy (such as radiation or surgery) would be appropriate for a patient. Radiation therapy can be used to target painful bone metastases, to prevent further tumor growth, and to relieve pain. Surgery may be performed on bones with impending fractures, spinal cord compression, or brain metastases for palliation. These modalities of treatment only affect the local site of disease, so a combination of local and systemic therapy would need to be administered to fully treat the patient. If a patient is experiencing worsening symptoms such as shortness of breath because of lung metastases or increased abdominal pain because of liver metastases, the use of chemotherapy may be preferred over hormonal therapy because of its quicker onset of action.[25,81]

Disease recurrence >5 years after diagnosis illustrates a more indolent-growing disease and is a favorable prognostic factor. Tumors with ER- and/or PR-positive characteristics would also be considered a good prognostic factor. Once therapy is initiated, response to therapy should be monitored periodically. Tumor markers such as CA.27.29 and CA.15.3 can be monitored in metastatic breast cancer. A clinical examination in combination with radiologic tests and tumor markers is assessed to determine response to therapy. Based on T.R.'s metastatic bone disease and ER/PR-positive tumor characteristics, the use of hormonal therapy would be the most appropriate agent to initiate. T.R. received tamoxifen therapy in the adjuvant setting. Because she progressed after taking tamoxifen therapy, this would not be reinitiated.

Case 97-4, Question 2: T.R. is started on anastrozole 1 mg orally daily with palbociclib 125 mg orally on days 1–21 and then 7 days off. What are other hormonal agents that can be used in the treatment of metastatic breast cancer?

Hormonal therapy in the metastatic setting can provide long progression-free survival in patients. If the patient responds for an extended period, the likelihood of response to another hormonal agent is high.[81,82] A patient may take multiple hormonal therapies before ever having to receive chemotherapy. As before, the decision regarding which hormonal agent to use is based on one's menopausal status. If the patient is premenopausal, the options include tamoxifen and LH-RH agonists; however, if the patient has received an SERM in the adjuvant setting, this would not be used again in the metastatic setting. Aromatase inhibitors are indicated for use in first-line therapy in the metastatic setting for postmenopausal females. If an AI is chosen as the first-line agent in the metastatic setting, use of another AI after progression would include one from another category (eg, nonsteroidal vs steroidal AI). For example, if anastrozole was used as first-line therapy for metastatic disease, then when the patient progresses, exemestane can be used. Aromatase inhibitors alone have been the standard front-line option for postmenopausal patients until the approval of the CDK 4/6 inhibitors. This class of drugs have single-handedly changed the approach to hormonal therapy in the metastatic setting for postmenopausal individuals with ER-positive, HER2-negative disease.

The CDK 4/6 inhibitors (palbociclib, ribociclib, and abemaciclib) work to form a complex with cyclin D and promote the transition from the G1- to S-phase in the cell cycle. These CDK 4/6 kinases are activated in ER-positive breast cancers, and they play an important role in reversing acquired resistance to previous hormonal therapy.[25,82] The PALOMA-2 trial was the first trial demonstrating overall improvements in progression-free survival with the combination of palbociclib and letrozole used in the first line, metastatic setting for ER and/or PR-positive disease.[83] Results demonstrated improvements in progression-free survival of 24.8 months with combined therapy versus 14.5 months with letrozole alone (95% CI, 12.9–17.1) and improvements in rates of disease progression or death (HR = 0.59; 95% CI, 0.46–0.72; $P < .001$). Myelosuppression is now a well-known toxicity with this class of

drugs, and in this trial, 66.4% of patients in the combination group experienced grade 3 or 4 neutropenia compared to 1.4% with letrozole alone, whereas only 1.8% in the combination arm experienced febrile neutropenia compared to 0.5% in the single arm group. All the CDK 4/6 inhibitors have been approved in both first-line and second-line settings for individuals with ER-positive, HER2-negative disease. See **Table 97-7** for a listing of the dosing recommendations with each agent and each combination of therapy.[82–85]

Table 97-7
Commonly Used Hormonal Regimens in the Metastatic Setting

Regimen	Dose
First-line Recommendation	
AI + CDK 4/6 inhibitor[a]	AI of choice + (one of the following): a. Palbociclib 125 mg orally daily × 21 days, then 7 days rest b. Ribociclib 600 mg orally daily × 21 days, then 7 days rest c. Abemaciclib 150 mg orally twice a day
Fulvestrant ± anastrozole or letrozole[b]	Fulvestrant: 500 mg IM on days 1, 15, 29 and then monthly + either anastrozole 1 mg orally daily or letrozole 2.5 mg orally daily
Fulvestrant + CDK 4/6 inhibitor[a]	See above for dosing recommendations
AI single agent[b]	See above for dosing of anastrozole and letrozole or use exemestane 25 mg orally daily
SERM single agent[b]	Tamoxifen 20 mg orally daily or toremifene 60 mg orally daily
Second-line Recommendation	
Fulvestrant + CDK 4/6 inhibitor if not previously used[a]	See above for dosing recommendations
Everolimus + endocrine therapy[b]	Everolimus 10 mg orally daily + Exemestane or tamoxifen or fulvestrant (see dosing above)

Regimen	Dose
First-line Recommendation	
AI single agent[b]	See above for dosing recommendations
Fulvestrant single agent[b]	See above for dosing recommendations
SERM single agent[b]	See above for dosing recommendations

IM, intramuscularly.

[a]Source: de Groot AF, Kuijpers CJ, Kroep JR, et al. CDK4/6 inhibition in early and metastatic breast cancer: a review. *Cancer Treat Rev*. 2017;60:130–138.

[b]Source: Rugo HS, Rumble RB, Macrae E, et al. Endocrine therapy for hormone receptor–positive metastatic breast cancer: American Society of Clinical Oncology guideline. *J Clin Oncol*. 2016;34(25):3069–3105.

Many other hormonal agents are available for use. The pure anti-estrogen, fulvestrant, is the only drug in a unique category of agents. It exerts its mechanism via binding and blocking of the ER and downregulates the number of ERs. Fulvestrant is administered as an intramuscular injection and is dosed initially as 500 mg on days 1, 15, and 29, then 500 mg monthly.[86,87] It is approved for use after failure of tamoxifen therapy in the metastatic setting.[86,87] This is an alternative for patients with compliance issues because of its once-monthly intramuscular dosing. See **Table 97-7** for common dosing and combinations. Other hormonal agents used in metastatic disease are megestrol acetate, progestins, and high-dose estrogens (higher doses have been found to inhibit cancer cell growth). These agents were used routinely before the approval of AIs and CDK 4/6 inhibitors and are now reserved for use after multiple hormonal therapy failures because of the toxicities associated with these therapies such as weight gain, vaginal bleeding, and thromboembolic events.[25]

With the advent of the CDK 4/6 inhibitors and the positive results for use in the first-line metastatic setting, other combination therapies have now become therapies of choice for the second-line, metastatic setting. One drug used in the second-line setting is everolimus, from the class of mTOR (mammalian target of rapamycin) inhibitors. This

agent has demonstrated the ability to block resistance pathways of endocrine therapy.[88] In the BOLERO-2 trial, patients who had failed previous AI therapy were randomized to everolimus 10 mg orally daily plus exemestane 25 mg orally daily versus exemestane plus placebo.[89] Progression-free survival was statistically significantly better in the combination arm, but follow-up overall survival results did not demonstrate the same results.[88,89] Food and Drug Administration (FDA) approval was granted to this combination therapy in the metastatic setting after patients have failed a nonsteroidal AI.

T.R. was started on anastrozole plus palbociclib therapy. If her disease progresses, options include exemestane plus everolimus, or fulvestrant, and then other agents such as megestrol acetate, high-dose estrogens, or androgens. The goal is to continue T.R. on multiple lines of hormonal therapy (as long as she is responding) before administering chemotherapy.

Prevention of Skeletal Events

Case 97-4, Question 3: In addition to hormonal therapy, what other supportive care medicines should be added to T.R.'s regimen?

Patients with bone metastases are commonly treated with bisphosphonate therapy to decrease the risk of skeletal-related events (ie, pathologic fractures, spinal cord compression, need for surgery, or radiation to the bone). Bisphosphonates act by inhibiting bone resorption. This ultimately will halt osteoclastic activity leading to stabilization of bony involvement, prevention of fractures, and reduction in calcium levels.[90,91] Bisphosphonates used are pamidronate 90 mg intravenously (IV) for 2 hours or zoledronic acid 4 mg IV for 15 minutes. Either of these agents can be administered once a month. Bisphosphonates are typically well-tolerated, although they may cause nausea, increased bone pain, and fever. Reduced doses should be used in patients with underlying renal dysfunction. A more well-known but uncommon side effect is osteonecrosis of the

jaw.[92] The mechanism by which this occurs is not fully understood, but prevention is critical. If dental extractions or surgery is needed, patients should not be initiated on bisphosphonate therapy until these procedures are completed. If these procedures are required after initiation of therapy, an oral maxillofacial surgeon should be consulted.[92]

Another agent approved for use in the prevention of skeletal-related events in solid tumors is the humanized monoclonal antibody, denosumab. This therapy offers a unique mechanism of action, targeting the RANK ligand, which is a mediator in osteoclast activity. Inhibition of osteoclastic activity by denosumab reduces bone pathology in osseous metastases. Denosumab has been compared prospectively with zoledronic acid in patients with metastatic breast cancer and demonstrated significant delays in and prevention of skeletal-related events.[93] Denosumab is administered as a subcutaneous injection and is given once a month. It has similar toxicities to zoledronic acid, but the dose does not require adjustments for declining renal function. Denosumab has been added to the American Society of Clinical Oncology guidelines for the prevention of skeletal events in metastatic breast cancer and other solid tumors.[94] T.R. can start on bisphosphonate therapy with zoledronic acid 4 mg IV or denosumab 120 µg subcutaneous (SC) once a month to help prevent skeletal-related events.

Progression of Disease

Case 97-4, Question 4: T.R. has a long progression-free survival on hormonal therapy. Over the course of 4 years, she progresses on anastrozole and palbociclib, then fulvestrant, then exemestane plus everolimus, and eventually, megestrol acetate. Each time she has progressed, the progression-free interval has shortened. Follow-up staging tests now reveal new liver lesions measuring 1 cm × 1 cm and 2 cm × 1 cm. A CT scan of the chest was negative. She is not currently experiencing any symptoms of her disease. What should the treatment course include now that T.R. has progressed after numerous lines of endocrine therapy?

Because T.R. has progressed through multiple lines of hormonal therapy and the progression-free interval has shortened with each treatment course, chemotherapy would now likely be the best option. Patients with a good performance status, little previous treatment, prolonged progression-free intervals, and limited metastatic disease are more likely to respond to further treatment with chemotherapy.[25,81] Chemotherapy is continued as long as the person is receiving benefit and is tolerating toxicities associated with treatment. If the disease progresses or the toxicities become intolerable, therapy should be changed or stopped. Patients experiencing toxicities may be placed on a chemotherapy holiday until toxicities are resolved or until therapy is tolerable.

In the metastatic setting, stabilization of disease and palliation of symptoms are considered when deciding what chemotherapy regimen to use. Sequential (single agent) versus combination chemotherapy should be discussed. Combination chemotherapy is generally associated with more toxicities than sequential treatment; however, it provides improved response rates.[25,95–97] Patients with substantial symptoms from their disease may initially be given combination therapy to rapidly shrink the tumor. Combination therapies that have demonstrated improvements in survival are docetaxel and capecitabine, paclitaxel and gemcitabine, and doxorubicin and paclitaxel.[95–97] Based on T.R.'s lack of symptoms, sequential therapy would be the best option for her at this time. This would offer her less toxicity and reserve other chemotherapeutic agents for the future.

Chemotherapy decisions can be very complex. There is no one standard regimen, and decisions should be made on an individual basis based on the patient's prior treatment, concurrent comorbidities, and time from adjuvant therapy to metastatic disease.

Most individuals today will have received anthracycline and taxane chemotherapy in the adjuvant setting. If the patient's disease recurs quickly after adjuvant therapy (ie, <1 year), the disease is considered resistant to that treatment and different agents should be selected. If a patient receives adjuvant paclitaxel and progresses on therapy, there are data to support the use of docetaxel in the treatment of

metastatic disease because of the lack of cross-resistance between taxanes.[98,99] Other chemotherapeutic agents with mechanisms similar to taxanes, such as eribulin or ixabepilone, have been approved for use in previous taxane failures. These agents offer additional options to patients who had responded to previous therapies.[25]

Previous toxicity is also considered when selecting therapy. In patients with preexisting neuropathies either from diabetes or previous chemotherapy, taxanes may not be an appropriate choice because these agents can also cause neuropathy. Additionally, capecitabine may be chosen over intravenous chemotherapy because this agent is administered orally. **Table 97-8** provides a list of commonly used agents/regimens in the metastatic setting. Clinical trials are always an option for patients if they have a good performance status. Many clinical trials are available and should be discussed with the patient if clinical trials are a possibility. Because T.R. has received an anthracycline and taxane agent in the adjuvant setting, an agent such as capecitabine would be an appropriate choice. This is an oral agent and also has the indication for first-line treatment of metastatic disease after failure of anthracycline and taxane chemotherapy.

Table 97-8
Commonly Used Chemotherapy Agents in the Metastatic Setting

HER2-Negative	
Sequential or single agent	Doxorubicin, epirubicin, liposomal doxorubicin, paclitaxel, docetaxel, capecitabine, vinorelbine, gemcitabine, albumin-bound paclitaxel, eribulin, ixabepilone
Combination chemotherapy	AC, EC, CMF, GT docetaxel/capecitabine, gemcitabine/carboplatin, paclitaxel/bevacizumab, carboplatin/paclitaxel or albumin-bound paclitaxel
HER2-Positive	
Chemotherapy + trastuzumab	Pertuzumab/trastuzumab/docetaxel, pertuzumab/trastuzumab/paclitaxel

HER2-Negative	
Other chemotherapy options combined with trastuzumab or other HER2 targeted therapy	Trastuzumab/paclitaxel/carboplatin Trastuzumab/docetaxel; trastuzumab/vinorelbine; trastuzumab/capecitabine; trastuzumab/tucatinib/capecitabine; ado-trastuzumab emtansine; fam-trastuzumab deruxtecan; lapatinib/capecitabine; trastuzumab/lapatinib; neratinib/capecitabine

A, doxorubicin; C, cyclophosphamide; E, epirubicin; F, fluorouracil; G, gemcitabine; M, methotrexate; T, paclitaxel.

Biologic and Other Targeted Therapies

Case 97-4, Question 5: Would T.R. be a candidate for any biologic therapy for the treatment of her metastatic breast cancer if she was HER2-positive?

Trastuzumab revolutionized the treatment of HER2-positive breast cancer. First in the metastatic setting, and now in the neoadjuvant and adjuvant settings.[25,49–51] Newer biologic therapies are also available for use in the metastatic setting. Trastuzumab is a fully humanized monoclonal antibody that binds to the extracellular HER2 receptor and works via antigen-dependent cellular cytotoxicity. When chemotherapy alone was compared with chemotherapy plus trastuzumab in HER2-positive metastatic breast cancer, the addition of trastuzumab therapy significantly increased survival.[49] This was the first study of its kind using biologic therapy and demonstrating survival benefit in metastatic breast cancer. Current practice is to continue the trastuzumab in patients who progress on a chemotherapy regimen but switch to an alternative chemotherapy agent.

As with all chemotherapeutic agents, breast cancer can become resistant to therapy. Trastuzumab provides significant improvement

in overall survival for patients with HER2-positive disease; however, trastuzumab resistance occurs. Newer pathways and resistance patterns have been identified to help clinicians understand the complexity of this disease. Two therapies are now approved for use in patients with HER2-positive disease.[100] Pertuzumab offers a novel mechanism of action for patients with HER2-positive disease. This agent is a monoclonal antibody similar to trastuzumab but blocks the extracellular domain on the HER2 receptor and blocks ligand-dependent heterodimerization with HER1, HER3, and HER4. The binding is different from trastuzumab in that trastuzumab binds to domain IV, whereas pertuzumab binds to domain II of the HER2 receptor. The CLEOPATRA trial evaluated pertuzumab in combination with docetaxel and trastuzumab versus docetaxel and trastuzumab plus placebo for the first-line treatment of metastatic breast cancer.[101] At a median follow-up of 50 months, the pertuzumab arm demonstrated improved overall survival (OS) of 56.5 months versus 40.8 months in the docetaxel + trastuzumab arm (HR, 0.68; 95% CI, 0.56–0.84; $P > .001$). Those treated with pertuzumab experienced more diarrhea, rash, mucosal inflammation, and febrile neutropenia.[101] Pertuzumab is approved for use in the first-line metastatic setting, neoadjuvant and adjuvant settings in combination with chemotherapy and trastuzumab.

Because pertuzumab does target the HER2 receptor, there is a concern regarding cardiac toxicity associated with its use. In the cardiac assessment of the CLEOPATRA trial, the incidence of cardiac adverse events (all grades) was similar between arms: 16.4% versus 14.5% in the placebo arm and the pertuzumab arm, respectively. Most patients experienced asymptomatic decreases in left-ventricular ejection fraction that resolved upon removal of the drug.[102]

Ado-trastuzumab emtansine (also known as TDM-1) is a unique formulation of an antibody–drug conjugate: Trastuzumab linked to DM1, a maytansine derivative. Maytansine is a potent microtubular inhibitor. Once the drug binds to the HER2 receptor, it is internalized and then undergoes degradation, releasing the cytotoxic agent to induce apoptosis. This agent was approved based on the results

from the EMILIA trial comparing ado-trastuzumab to capecitabine and lapatinib in patients who had failed previous taxanes and trastuzumab.[103] Ado-trastuzumab improved both progression free survival (PFS) and OS. Common toxicities for this agent include peripheral neuropathy, fatigue, anemia, increased liver enzymes, and myelosuppression. As with other HER2-targeted therapies, the concern for cardiac toxicity was evaluated. Less cardiotoxicity was identified in the ado-trastuzumab group compared to the combination arm (1.8% vs 3.3%, respectively). This drug's name is very similar to traditional trastuzumab and hence the FDA recommendation for the addition of the prefix ado- to the name.[104] The approved indication of this agent includes use in patients with HER2-positive metastatic breast cancer who have previously received trastuzumab and a taxane, separately or in combination.

If the patient, T.R., had HER2-positive disease, a common first-line regimen to use in the metastatic setting would be pertuzumab plus trastuzumab in combination with docetaxel based on the data from the CLEOPATRA trial.[101]

If a patient presented with metastatic triple-negative breast cancer, there is now an approved regimen for use first line. Based on the Impassion 130 trial, patients were randomized to receive atezolizumab plus nab-paclitaxel compared to nab-paclitaxel plus placebo and stratified based on PD-L1 status.[105] The primary end points included both progression-free and overall survival. Among those patients who had PD-L1–positive disease, the median PFS was 7.5 versus 5 months (HR = 0.62, 95% CI, 0.49–0.78, $P < .001$) and the median overall survival was 25 versus 15.5 months (HR = 0.62; 95% CI, 0.45–0.86). Patients did better with atezolizumab added to their regimen even if they did not express PD-L1.[105] This combination now offers a specific treatment approach when faced with a patient with triple-negative, PD-L1–positive disease in the first-line metastatic treatment setting.

Other unique targeted therapies are being evaluated in metastatic breast cancer. One new indication has been granted to alpelisib for use in individuals with phosphatidylinositol 3-kinase (PI3K) mutations and ER- and/or PR-positive breast cancer. The incidence of this

mutation is ~40% of patients.[106] The SOLAR-1 study group evaluated alpelisib 300 mg orally daily plus fulvestrant compared to fulvestrant alone. At a median follow-up of 20 months, the progression-free survival was 11 versus 5.7 months (HR = 0.65, 95% CI, 0.50–0.85; *P* < .001). Adverse effects attributed to alpelisib included hyperglycemia, diarrhea, and rash.[106] This offers another option for those who have relapsed disease or in those who have progressed during or after endocrine therapy.

With breast cancer, there are always new drugs and/or combinations being approved for the treatment of early- and late-stage disease. As data progress, the likelihood is that the treatment schema will change. More and more data are evaluating neoadjuvant and adjuvant uses of CDK 4/6 inhibitors.[84] Soon these agents may be commonly used in these settings. In addition, further data may shed more light on treatment modalities for those diagnosed with triple-negative disease and how immunotherapy may evolve for those diagnosed with breast cancer.[107]

Lung Cancer

Maryann R. Cooper

CORE PRINCIPLES		CHAPTER CASES
1	Non-small-cell lung cancer (NSCLC) and small-cell lung cancer (SCLC) together account for more cancer-related deaths than any other malignancy for both males and females. Smoking is the biggest risk factor and is proportional to the number of pack-years. For former smokers, the risk for developing the disease decreases over time after smoking cessation.	**Case 98-1 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
2	Chances for survival are increased for those whose disease is detected early. The U.S. Preventive Services Task Force recommends annual screening with low-dose computed tomography in patients 55–80 years old with at least a 30-pack-year smoking history in current smokers or those who have quit within 15 years as this did increase detection and improve survival.	**Case 98-1 (Question 1), Table 98-3**
3	The initial signs and symptoms vary according to location and stage of the disease. Many patients are asymptomatic upon initial diagnosis, or signs and symptoms may be masked by other concurrent conditions such as chronic obstructive pulmonary disease.	**Case 98-1 (Question 2) Case 98-2 (Question 1), Table 98-1**
4	Surgery, radiotherapy, chemotherapy, targeted therapy, and immunotherapy are all modalities used in the treatment of NSCLC. Treatment decisions are individualized according to disease stage, tumor histology (eg, adenocarcinoma, squamous), presence or absence of molecular marker mutations (eg, epidermal growth factor receptor [EGFR], programmed death-ligand 1 [PD-L1]), performance status, comorbidities, and patient preference.	**Case 98-1 (Questions 2, 3) Case 98-2 (Questions 1–6), Tables 98-4–98-6**

CORE PRINCIPLES		CHAPTER CASES
5	SCLC tumors generally have a higher proliferation rate than NSCLC tumors. Hence, chemotherapy, radiotherapy, and immunotherapy are the primary treatments. These tumors tend to grow more centrally and rapidly than NSCLC tumors; therefore, surgical resection is usually not performed.	**Case 98-3 (Questions 1–4)**
6	Most NSCLC cytotoxic chemotherapy regimens are cisplatin-based or carboplatin-based doublets with or without an immune checkpoint inhibitor. These are given for four to six cycles. Maintenance therapy has been shown to be beneficial for patients receiving cytotoxic chemotherapy with or without an immune checkpoint blockade. Targeted therapies are currently limited given the infrequency at which genetic variations are discovered.	**Case 98-1 (Question 3) Case 98-2 (Questions 1–3), Tables 98-4–98-6**
7	Most SCLC cytotoxic chemotherapy regimens are cisplatin-based or carboplatin-based doublets in combination with etoposide and an immune checkpoint inhibitor if extensive-stage disease.	**Case 98-3 (Questions 3–6)**

INTRODUCTION

Lung cancers may be referred to as non-small-cell lung cancer (NSCLC) or small-cell lung cancer (SCLC), and although there are many similarities between these two, treatments will often differ. Approximately 85% of lung cancers are classified as NSCLC and the remaining are classified as SCLC.[1] This chapter will initially focus on the presentation, diagnosis, and treatment of NSCLC, followed by a shorter section that describes SCLC.

Non-Small-Cell Lung Cancer

Epidemiology

Incidence of lung cancer in the United States is second to prostate cancer in males and breast cancer for females. Lung cancer is the leading cause of death relative to all of the other cancers. As with most solid tumors, survival is better for patients diagnosed with early-stage disease than it is for those with more advanced disease.[2] However, for many patients, the disease often goes undetected either because of the lack of noticeable symptoms or because they may be masked by concurrent diseases with similar symptoms such as chronic obstructive pulmonary disease (COPD).

PATHOPHYSIOLOGY

NSCLC tumorigenesis is a multistep process in which neoplastic tissue arises from bronchial epithelium. These cells, which form the inner lining of bronchial tissue, develop genetic lesions to proto-oncogenes and tumor suppressor genes, resulting in the dysregulation of key molecular signaling pathways. As a result, cellular proliferation occurs and responsiveness to apoptotic signaling is often diminished. Eventually, accumulation of additional genetic abnormalities can influence the cell's ability to metastasize, resulting in the spread of tumorous tissue locally or to more distant sites in the lymph nodes and organs.

Non-small-cell lung tumors are classified further according to tumor tissue histology. The three major histologic types include squamous cell carcinoma, adenocarcinoma, and large-cell

carcinomas. Although these different variants were identified several decades ago, recently it has been demonstrated that the histology impacts chemotherapeutic agent selection. These three may be subcategorized further and other variants of NSCLC also exist; however, discussion in this chapter will be limited to these three. The adenocarcinomas and large-cell carcinomas are commonly grouped together as nonsquamous carcinomas. These tumors commonly arise in the periphery of the lung and the smaller airways. After various periods of growth in the lung parenchyma or bronchial wall, these primary tumors invade the vascular and lymphatic system, enabling metastases to regional lymph nodes and more distant sites.[1]

RISK FACTORS AND CLINICAL PRESENTATION

There are several risk factors for developing lung cancer, but the biggest factor is cigarette smoking, which is estimated to increase the risk by up to 30-fold. The prevalence of smoking peaked in the early 1960s and has steadily decreased in the United States because of increased awareness of the harm of smoking. Death rates from lung cancer in both males and females have also followed this downward trend. For males, deaths because of lung cancer peaked in the 1980s and has since steadily decreased. For females, deaths because of lung cancer began to decline in the mid-2000s. Other risk factors include secondhand smoke, cigar and pipe smoking, occupational and environmental exposures, radon, asbestos, certain metals such as chromium and cadmium, various organic chemicals, radiation, air pollution, history of tuberculosis, and genetic factors. The latter appears to be related to those who exhibit the disease early in life. The probability of developing invasive lung cancer increases with age and peaks during the seventh decade of life.[2–4]

The disease is detected either when a person presents with signs and symptoms commonly associated with lung cancer or, by chance, when the patient is under evaluation for other disorders or procedures. Selected signs and symptoms are listed in **Table 98-1**,

but vary widely between patients according to tumor size, stage, and location.

Table 98-1
Common Selected Signs and Symptoms for Lung Cancer

Cough
Hemoptysis
Wheeze
Dyspnea
Pain (eg, chest wall)
Obstruction of vital structures (eg, esophagus, superior vena cava)

Symptoms are highly dependent on tumor size, location within the chest cavity, and presence of metastases.

DIAGNOSIS

If a malignancy comes under consideration, a computed tomography (CT) or positron emission tomography (PET)–CT scan of the abdomen and thoracic region is usually performed to identify any possible primary lesions and to look for possible metastases to lymph nodes and other organs or contralateral lung. If located, a pathologic evaluation is performed to confirm the diagnosis. Magnetic resonance imaging (MRI) of the head may be ordered if brain metastases are suspected. Preoperatively, specimens may be obtained through methods such as bronchial brushings, bronchial washings, fine-needle aspiration biopsy, core needle biopsy, endobronchial biopsy, and transbronchial biopsy. Mediastinal lymph nodes are also sampled via mediastinoscopy to determine staging. If surgery is performed, specimens are evaluated during the procedure to determine the resection margin status, diagnose incidental nodules discovered during surgery, and sampling of regional lymph nodes. Postoperative evaluation provides pathology characteristics necessary for classifying tumor type and staging.[1]

Staging is performed to determine prognosis and to guide treatment decision-making. In general, the prognosis declines with increasing disease stage at initial diagnosis. Five-year overall survival rates are 54% for patients with disease that is locally limited

and 4% for metastatic disease. For all stages, 5-year overall survival has only marginally improved over the last 30 years to 18%. Unfortunately, the disease has already metastasized in >50% of patients upon initial presentation. However, earlier detection with spiral CT has resulted in a decrease in disease-related death in patients with at least a 30-pack-year smoking history.[2,4,5] Staging classification is reliant on anatomic characteristics and was updated by the International Association for the Study of Lung Cancer (IASLC) and adopted by the American Joint Committee on Cancer (AJCC). The AJCC 8th edition staging manual was implemented in the United States in January, 2018.[6,7] In addition to the tumor, node, metastases (TNM) stage, molecular markers and tumor histology are key information in making treatment decisions. **Table 98-2** illustrates how the TNM classification is used to determine the clinical stage.

Table 98-2
Clinical Staging for Non-Small-Cell Lung Cancer

Clinical Stage	Tumor Characteristics
Stage I	Tumor ≤5 cm in greatest diameter with no nodal involvement
Stage II	Tumor >5 cm, but ≤7 cm in greatest diameter with no nodal involvement Tumor ≤7 cm with adjacent lymph nodes involved Tumor >7 cm or invading local structure (ie, chest wall) with no nodal involvement
Stage III	Any tumor size with adjacent lymph nodes involved or ipsilateral mediastinal and/or subcarinal lymph nodes Tumor invading mediastinum, heart, great vessels, esophagus, or another tumor nodule in different ipsilateral lobe
Stage IV	Any tumor size, any nodal involvement and metastasis to the contralateral lobe, malignant pleural effusions, or distant metastasis

OVERVIEW OF TREATMENT

Surgery, radiation, and systemic therapy (ie, cytotoxic chemotherapy, targeted therapy, and immunotherapy) are all treatment modalities used in the treatment of NSCLC. If diagnosed in the early stages of the disease, surgery offers the best chance of cure. Chemotherapy, targeted therapies, and immune therapies are associated with enhanced survival depending on the stage of disease and patient characteristics. The remaining discussion of NSCLC in this chapter will outline the key aspects in the treatment of early and late stages of the disease.

Early-Stage Non-Small-Cell Lung Cancer

CASE 98-1

Question 1: A 69-year-old male patient, J.W., was found to have a 3-cm nodule on a chest x-ray done prior to an elective cataract surgery. The patient was a lifelong cigarette smoker, having started smoking in his early 20s, approximately one pack of cigarettes per day. He quit smoking 9 years ago.

What screening methods might be available to detect the disease in asymptomatic patients? What risk factors does J.W. have for lung cancer?

The National Lung Screening Trial (NLST) was a randomized study comparing low-dose CT (LDCT) scans with chest radiography in over 50,000 patients with a heavy smoking history, examining lung cancer mortality.[8,9] The NLST did result in a higher incidence of confirmed diagnoses of lung cancer with LDCT, resulting in a 20% relative reduction in the rate of death from lung cancer. LDCT did result in a higher rate of false positives than chest radiography.[5] When combined with smoking cessation, screening with LDCT results in a 38% decrease in lung cancer mortality.[10] Results of the NLST support the U.S. Preventive Service Task Force recommendations of annual screening for lung cancer with low-dose CT scans in adults 55 to 80 years old with a 30-pack-year smoking history and currently smoke or have quit within the last 15 years.[11]

The probability for developing the disease increases with age, and J.W.'s age is close to the median age of peak incidence. Males also

have a slightly higher risk than females, as discussed. Smoking is the largest risk factor for lung cancer development; however, what if a person stops smoking? Does the risk decrease with time? These questions are important for health care providers to address as they are encouraging smoking cessation for their patients. In J.W.'s case, he stopped 9 years ago, so what impact would this smoking history have on development of the disease? In general, people who stop smoking, even well into middle age, avoid almost 90% of the risk attributable to tobacco. Shown in **Table 98-3** are data demonstrating the relation between the age at which a person stops smoking and the cumulative percent risk (at age 75) for developing lung cancer.[12] J.W. stopped when he was ~60 years old; therefore, based on this table, the cumulative risk would approach 10% if he were 75 years old. Because he is 69 years old, his risk would be decreased but not to the extent that it would if a longer period of time had elapsed. If he were still smoking, the risk would be expected to be closer to 16%. Hence, smoking cessation is an effective means for lowering the risk over time. He smoked for ~35 to 40 pack-years, so the total number of cigarettes would also increase his risk. According to data from the same studies, risk of disease for a one pack per day smoker would be approximately twice that of someone who smoked less than a half pack per day. Survival from the disease is also better for nonsmokers than for smokers.[12,13]

Table 98-3

Cumulative Risk (%) of Death From Lung Cancer at Age 75 Years

Smoking Status	Risk at Age 75
Lifelong nonsmoker	>1
Stopped at age 30	>2
Stopped at age 40	3
Stopped at age 50	6
Stopped at age 60	10
Continuing smoker	16

Frequently, patients will experience remorsefulness for having smoked, but it is never possible to attribute one's disease to a single factor such as smoking. In fact, 90% of smokers never exhibit symptoms of the disease. Furthermore, 15% of males and 53% of all females with lung cancer worldwide are never smokers.[14] This suggests that other factors such as genetics are associated with the development of the disease. Research has been directed at identifying genomic associated factors that have the potential to lead to the development of lung cancer in both smokers and nonsmokers. It has been shown that there can be some genetic associations, but the true impact of these genetic polymorphisms has not been fully elucidated.[3,15–18]

A more thorough history from J.W. would be helpful, but recall for exposure to pollution, chemicals, and secondhand smoke exposure is difficult to quantify. Hence, the view held by much of society that lung cancer is a self-inflicted disease is not entirely true. In summary, there is limited history on J.W.'s exposure to environmental hazards such as radon and secondhand smoke. His age is close to that of peak incidence. Although he stopped smoking almost a decade ago, there is still some residual risk associated with past smoking history, and this would be expected to be higher for those with many pack-years history. Because of his heavy smoking history, J.W. may have benefited from low-dose CT scan screening to potentially provide earlier detection of lung cancer.

Case 98-1, Question 2: A CT scan was ordered for further evaluation, and it showed an isolated spiculated nodule in the right upper lobe with no mediastinal or hilar adenopathy. The nodule showed no calcification. A CT-guided needle biopsy was performed that showed a well-differentiated adenocarcinoma consistent with a primary NSCLC. Further staging was carried out with PET–CT scanning that demonstrated no additional areas of disease except for the nodule. What would be the best treatment plan for J.W., given the current information? Would surgery or neoadjuvant therapy be indicated?

The goal of therapy for this patient is to achieve a cure, especially because the disease appears to be early stage. Surgery is the best treatment modality for patients with stages I and II disease because

these tumors are limited to one hemithorax and can be readily removed by excision. In most instances, lobectomy using a minimally invasive technique (eg, video-assisted thoracic surgery [VATS]), with node dissection is sufficient for local control. During surgery, the mediastinal lymph nodes are sampled for presence of the disease and to confirm staging. J.W. appears to have limited disease, and so minimally invasive lobectomy would be recommended for him. For patients whose primary tumor or lymph node involvement extends to the proximal bronchus or proximal pulmonary artery, or crosses the major fissure, then a more extensive sleeve resection would be performed. For patients with a medical contraindication to surgery, curative radiation therapy can be used in place of surgery. However, surgery is the treatment of choice, and final staging during surgery will guide adjuvant treatments.[19] Neoadjuvant therapy may be recommended to reduce the tumor burden prior to surgery depending on tumor size and location within the lung. If neoadjuvant therapy is chosen, the regimen is usually similar to those used in the adjuvant setting (**Table 98-4**).[20-29] Therefore, surgery is the primary treatment modality for patients with stages I, II, and select stage IIIA disease. J.W.'s disease appears to be localized; therefore, surgical removal of the tumor would be indicated, and neoadjuvant therapy would not be indicated because of the size and location of the primary tumor.[19]

Table 98-4

Adjuvant Chemotherapy Regimens for Non-Small-Cell Lung Cancer

Regimen	Schedule
Cisplatin, day 1[a] Pemetrexed, day 1[a]	Every 21 days for four cycles[20]
Cisplatin, day 1 Gemcitabine, days 1, 8	Every 21 days for four cycles[21]
Cisplatin, day 1 Docetaxel, day 1	Every 21 days for four cycles[22,23]

Regimen	Schedule
Cisplatin, days 1, 8 Vinorelbine, days 1, 8, 15, 22	Every 28 days for four cycles[24]
Cisplatin, day 1 Vinorelbine, days 1, 8, 15, 22	Every 28 days for four cycles[25,26]
Cisplatin, day 1 Vinorelbine, days 1, 8	Every 21 days for four cycles[24]
Cisplatin, day 1 Etoposide, days 1–3	Every 28 days for four cycles[26]
For patients unlikely to tolerate cisplatin	
Paclitaxel, day 1 Carboplatin, day 1	Every 21 days for four cycles[27]
Gemcitabine, day 1, 8 Carboplatin, day 1	Every 21 days for four cycles[28]
Pemetrexed, day 1[a] Carboplatin, day 1[a]	Every 21 days for four cycles[29]

[a]Nonsquamous cell only.

CASE 98-1, QUESTION 3: J.W. was referred to a thoracic surgeon for resection. A right upper lobe lobectomy was performed with lymph node dissection. The pathology report revealed a 3.2 × 4 cm adenocarcinoma with three associated peribronchial lymph nodes containing cancer cells. Lymph nodes sampled from the mediastinum demonstrated no cancer. The patient's tumor was staged as a T2N1M0 (stage IIA) NSCLC. Now that the tumor has been completely resected and staging of the disease is finalized, what additional therapy, if any, is recommended?

Although NSCLC tumors are minimally responsive to chemotherapy, evidence from several studies (Table 98-4) demonstrates that adjuvant treatment enhances patient survival and should be considered as part of the treatment plan for select patients. The Lung Adjuvant Cisplatin Evaluation (LACE) Collaborative Group conducted a meta-analysis of five randomized controlled trials that evaluated the use of adjuvant cisplatin-based chemotherapy in patients with completely resected NSCLC. Overall, a decreased risk of death was observed following adjuvant

chemotherapy (hazard ratio, 0.89 [95% confidence interval, 0.82–0.96]). However, the benefit was not consistent across stages. No statistically significant difference in death was seen in patients with stage IA (hazard ratio, 1.40 [95% confidence interval, 0.95–2.06]) and stage IB (hazard ratio, 0.93 [95% confidence interval, 0.78–1.10]) NSCLC. The benefit of this therapy was limited to those with completely resected stage II (hazard ratio, 0.83 [95% confidence interval, 0.73–0.95]) and stage III (hazard ratio, 0.83 [95% confidence interval, 0.72–0.94]) disease.[30] As summarized in Table 98-4, adjuvant chemotherapy utilizes cisplatin as the base of the regimen. A second agent, usually selected from one of those listed in Table 98-4, is added as doublet therapy, and the goal is for patients to receive four cycles. Toxicity often becomes worse beyond four cycles and benefits are diminished thereafter. Therefore, cytotoxic chemotherapy is beneficial but has its limitations. As demonstrated in the CALGB 9633 study, carboplatin plus paclitaxel also improves survival in those with stages II and IIIA NSCLC.[27] Therefore, carboplatin can be used as an alternative in patients unlikely to tolerate cisplatin.

Radiation therapy is frequently used in the treatment of malignancies, including later stages of NSCLC; however, it has no proven benefit for the treatment of early-stage disease. The postoperative radiotherapy trialists (PORT) Group conducted a meta-analysis from nine randomized trials to evaluate the possible role of postoperative radiotherapy in patients with completely resected NSCLC. There were 707 deaths among 1056 patients assigned postoperative radiotherapy and 661 among 1072 assigned surgery alone (hazard ratio, 1.21 [95% confidence interval, 1.08–1.34]). This 21% relative increase in the risk of death with radiotherapy is equivalent to a reduction in overall survival from 55% to 48%. Subgroup analysis showed that the increased risk of death was greatest for patients with stage I/II, N0 or N1, but no clear evidence for those with stage III, N2 disease.[31] Separately, another postoperative radiotherapy study was conducted, using data from 7465 patients in the Surveillance, Epidemiology, and End Results (SEER) database. The investigators for this study also found no

benefit for radiotherapy, especially for patients with N1 and N0 disease. However, an increase in survival was associated with radiotherapy for patients who had N2 disease.[32] Consequently, radiation therapy is reserved for patients with more advanced NSCLC.

In summary, adjuvant cytotoxic chemotherapy is recommended for patients with completely resected stage II or III NSCLC following surgery. Multiple prospective phase-3 studies have shown that platinum-based chemotherapy after surgery will increase the survival rate of patients after surgery by about 10%. Because J.W. has stage IIA disease, four cycles of a platinum-based doublet regimen would be indicated after surgery; however, he should not receive radiation therapy at this time.

Late-Stage Non-Small-Cell Lung Cancer

CASE 98-2

QUESTION 1: L.L., an 85-year-old female, presented with a mild cough, productive with nonbloody sputum, shortness of breath, and fever. She was initially seen by her primary care physician who treated her with antibiotics for possible pneumonia; however, chest radiography showed a persisting infiltrate in the left upper lung. This was later confirmed on a CT scan with the presence of a 6 × 3 × 3.6 cm mass in the left upper lobe. Mediastinal adenopathy and multiple pulmonary nodules were seen in the right upper lobe with associated scarring, the largest of them measuring 14 × 9 mm in the right upper lobe anteriorly. Transbronchial biopsy led to a diagnosis of adenocarcinoma. The tumor tissue was positive for a sensitizing *EGFR* mutation because of a deletion in exon 19. The PD-L1 tumor proportion score was 52%, and the sample was negative for other gene mutations and rearrangements. Because of the spread of disease to the contralateral lung, disease was staged as IV. Pertinent patient history included hypertension and hyperlipidemia. The patient also had a hemangioma of the brain resected in 1960 and a history of cervical cancer treated with an abdominal hysterectomy in 1962. She has never smoked. Upon evaluation, she was found to have a hemoglobin that was slightly low at 11.3 g/dL with a white blood cell count of 5200 cells/μL and a platelet count of 245,000/μL. The electrolytes showed normal sodium of 143 mEq/L, normal potassium of 4.4 mEq/L, and creatinine of 1.08 mg/dL, with estimated creatinine clearance of 48 mL/minute. Her performance status was 0 to 1.

What are the treatment options for patients such as L.L. with advanced (inoperable stages III and IV) disease?

SURGERY

In general, tumors in patients with stages III and IV disease are inoperable. These tumors often invade the carina, great vessels, vertebral bodies, more distant lymph nodes, metastases, and are frequently associated with malignant pleural effusions. Hence, combined-modality treatments such as cytotoxic chemotherapy and radiation or targeted therapies are the preferred treatments for patients with advanced-stage disease.[33,34] Surgery to remove solitary metastatic sites may also be considered in selected patients, especially in patients with a solitary brain metastasis.[35]

RADIATION AND CHEMOTHERAPY

Radiation therapy is the primary local treatment (ie, definitive radiation therapy) for inoperable nonmetastatic NSCLC and is also used as a palliative modality for patients with incurable disease with symptoms such as pain or shortness of breath. For tumors classified as stage III, radiation therapy is given concurrently with chemotherapy, as this has been shown to be superior to both radiation alone and also sequential radiation followed by chemotherapy.[36-41] The radiation dose, in combination with chemotherapy, usually ranges between 60 and 65 Gray (Gy), given in 2-Gy fractions. The recommended chemoradiation regimen for stage III disease is based on tumor histology. Histology is an important factor for individualizing treatment based on either safety or efficacy outcomes. Hence, once the biopsy is obtained, it is crucial to differentiate the histologic subtype (ie, squamous vs nonsquamous).[42] Many agents are effective against all histologic types such as cisplatin, carboplatin, gemcitabine, and paclitaxel. However, other agents such as bevacizumab and pemetrexed are only indicated for use in patients who have nonsquamous histology. Squamous cell histology is associated with increased risk for severe pulmonary hemorrhage compared with adenocarcinoma.[43] For

pemetrexed, significant association between improved efficacy and the nonsquamous subtype has been reported.[44,45] Therefore, for patients with nonsquamous histology (ie, adenocarcinoma or large cell), either cisplatin or carboplatin is combined with pemetrexed, etoposide, or paclitaxel. If the patient has squamous cell carcinoma, the preferred regimens contain cisplatin or carboplatin combined with etoposide or paclitaxel, respectively.[36-41,46] See **Table 98-5** for specific chemoradiation regimens. Durvalumab consolidation is offered to patients with stage III disease, a performance status 0 to 1, who do not experience disease progression after two or more cycles of definitive chemoradiation. Durvalumab consolidation significantly improves overall survival compared to placebo in this setting.[46]

Table 98-5
Representative Chemoradiation Regimens for Inoperable Stage III Non-Small-Cell Lung Cancer

Regimen	Schedule
Cisplatin, days 1, 8, 29, 36 Etoposide days 1–5, 29–33	Concurrent radiation of 45 Gy administered in 25 daily 1.8 Gy fractions over 5 weeks[36,37]
Carboplatin AUC 5, day 1 Pemetrexed, day 1 *Nonsquamous histology	Every 21 days for four cycles[38] Concurrent radiation of 70 Gy administered in 35 daily 2 Gy fractions over 6–7 weeks
Cisplatin, day 1 Pemetrexed, day 1 *Nonsquamous etiology	Every 21 days for three cycles[39,40] Concurrent radiation of 60–66 Gy in 30–33 daily 2 Gy fractions over 6–7 weeks With or without consolidative pemetrexed every 21 days for four cycles
Paclitaxel weekly for 7 weeks Carboplatin AUC 2 weekly for 7 weeks	Concurrent radiation of 60 Gy in 2 Gy fractions over 6–7 weeks With or without consolidative paclitaxel plus carboplatin every 21 days for two cycles[41]

Metastases may also be treated locally with radiation therapy. For example, brain metastases, spinal cord compression, and impending fractures of weight-bearing bones can be treated with radiation or surgery before systemic therapy commences. In contrast to patients with stage III disease, those with stage IV disease usually receive local treatment with radiation therapy, either before or after chemotherapy, because therapy given concurrently is often not well tolerated by patients with this stage of disease.

SYSTEMIC THERAPY

A deeper understanding of the pharmacogenomics and the immune microenvironment of NSCLC has led to a shift if the primary treatment of metastatic disease from traditional cytotoxic chemotherapy to targeted therapies. Several driver mutations and gene rearrangements have been discovered that when targeted, have demonstrated improved survival compared to chemotherapy. In addition, immune checkpoint blockade alone or in combination with chemotherapy has also been shown to improve survival.[47–49] Molecular and immune biomarker testing is recommended for most patients diagnosed with stage IV disease. Results of this testing will drive first-line treatment choice. See **Table 98-6** for first-line treatment recommendations.

Table 98-6
Representative Initial Therapy for Metastatic Non-Small-Cell Lung Cancer

Target	Preferred Initial Treatment	Alternate Treatment
EGFR	Osimertinib[61,62]	Erlotinib[47] Afatinib[64] Gefitinib[63] Dacomitinib[65] Erlotinib + ramucirumab[107] Erlotinib + bevacizumab[108]
ALK	Alectinib[109]	Brigatinib[110] Ceritinib[111]

ROS1	Crizotinib[112] or entrectinib[113]	Ceritinib[114]
BRAF V600E	Dabrafenib + trametinib[115]	Vemurafenib[116] Dabrafenib[117]
MET exon 14 skipping mutation	Capmatinib[118]	Crizotinib[119]
RET	Selpercatinib[120] or pralsetinib[121]	Cabozantinib[122] Vandetanib[123]
NTRK	Larotrectinib[124] or entrectinib[125]	
PD-L1 ≥ 1%[a]	Pembrolizumab[49,60] *PD-L1 ≥50% only Atezolizumab[127] *PD-L1 ≥ 50% only Carboplatin or cisplatin + pemetrexed + pembrolizumab[51] (nonsquamous only) Carboplatin + paclitaxel or *nab*-paclitaxel + pembrolizumab[69] (squamous cell only)	Carboplatin + paclitaxel + bevacizumab + atezolizumab[126] (nonsquamous only) Carboplatin + *nab*-paclitaxel + atezolizumab[126] Nivolumab + ipilimumab + pemetrexed + carboplatin or cisplatin[128] (nonsquamous cell only) Nivolumab + ipilimumab + paclitaxel + carboplatin[128] (squamous cell only) Nivolumab + ipilimumab[129]
PD-L1 < 1%[a]	Carboplatin or cisplatin + pemetrexed + pembrolizumab[51] (nonsquamous only) Carboplatin + paclitaxel or *nab*-paclitaxel + pembrolizumab[69] (squamous cell only)	Carboplatin + paclitaxel + bevacizumab + atezolizumab[126] (nonsquamous only) Carboplatin + *nab*-paclitaxel + atezolizumab[126] Nivolumab + ipilimumab + pemetrexed + carboplatin or cisplatin[128] (nonsquamous cell only) Nivolumab + ipilimumab + paclitaxel + carboplatin[128] (squamous cell only) Nivolumab + ipilimumab[129] Pembrolizumab[49,60]

[a]Must be negative for other driver mutations or gene rearrangements.

Patients receiving oral tyrosine kinase inhibitors (eg, osimertinib, alectinib) to target a specific driver mutation or gene rearrangement will receive therapy until disease progression. Subsequent therapy will depend on symptoms and location of disease. A tumor flare response may occur after discontinuation of tyrosine kinase inhibitor treatment. If a patient experiences such response, the tyrosine kinase inhibitor should be reinitiated.[50] Response to treatment will be evaluated initially after two cycles. Patients receiving an immune checkpoint inhibitor alone or in combination with chemotherapy will transition to maintenance therapy if there is a response or the patient achieves stable disease after four to six cycles. The intention of such additional treatment would be to prolong the response and survival made possible by first-line treatment. Maintenance therapy differs from second-line therapy in that second-line treatment is only used when the patient has progressed during or after first-line treatment or is unable to tolerate it. Continuation maintenance, which refers to the use of one of the agents given in the first-line setting, is preferred. Often, the immune checkpoint inhibitor alone is continued.[49] For adenocarcinoma, pemetrexed can be continued in combination with pembrolizumab if the first-line regimen consisted of carboplatin with pemetrexed and pembrolizumab.[51]

PALLIATION

Patients with metastatic NSCLC receive benefit from palliative care early after diagnosis, rather than waiting until end-of-life care. This palliative care includes helping the patient cope with the psychosocial aspects of their disease through methods such as counseling (eg, expectation of treatment outcomes and affordability of treatment). In a study of patients with metastatic disease, subjects were randomly assigned to receive either early palliative care integrated with standard oncologic care versus standard oncologic care alone. Patients assigned to early palliative care experienced a better quality of life and survival (11.6 vs 8.9 months) than patients assigned to standard care alone. They also experienced fewer depressive symptoms (16% vs 38%). The results show that palliative

care is appropriate and potentially beneficial when it is introduced at the time of diagnosis at the same time as other beneficial therapies.[52]

In conclusion, L.L. would not likely receive benefit from surgical removal of the primary tumor or metastatic site. Although the tumor sample expresses PD-L1, first-line therapy for a patient with a sensitizing *EGFR* mutation is *EGFR*-targeted therapy.

CASE 98-2, QUESTION 2: How often are actionable genetic alterations present, and what patient characteristics are associated with them?

A major advancement in the management of advanced and metastatic NSCLC has been the discovery of driver mutations and gene rearrangements that serve as targets for drug therapy. Targeted therapy directed at a genetic alteration is often more effective and is better tolerated compared to standard cytotoxic chemotherapy. As listed in Table 98-6, there are currently several genetic alterations with U.S. Food and Drug Administration (FDA)–approved targeted therapy. Despite the abundance of targeted drug therapy, gene rearrangements and driver mutations are infrequently discovered in patients diagnosed with advanced or metastatic NSCLC.

Of the currently known alterations, driver mutations in *EGFR* are most common, occurring in 10% to 40% of patients with NSCLC. Somatic *EGFR* mutations predominantly occur in females, never-smokers, those of East Asian descent, and those with adenocarcinoma histology.[53] *ALK* gene rearrangements occur in ~2% to 8% of patients. Like *EGFR* mutations, *ALK* gene rearrangements are discovered more often in patients with adenocarcinoma as well as those that were light or never smokers. This aberration occurs more frequently in younger, male patients.[54] Similarly, *ROS1* gene rearrangements are found most often in younger, male, never-smokers with adenocarcinoma. This gene rearrangement is present in up to 5% of patients with NSCLC.[54,55] *BRAF* mutations occur in about 3% of patients with adenocarcinoma.

Unlike the previously discussed alterations, *BRAF* mutations tend to be found in current or former smokers.[54] *MET* exon 14 skipping mutations are seen in 3% to 4% of patients with adenocarcinoma and 1% to 2% of patients with other histologies. These mutations are more frequently seen in older females who are never-smokers.[54,56] *RET* gene rearrangements occur in 1% to 2% of patients with adenocarcinoma and are seen in both smokers and nonsmokers.[54,57] *NTRK* gene fusions are extremely rare, occurring in 0.2% of patients with NSCLC.[58]

Despite the fact that certain histologies and patients characteristics are associated with genetic aberrations, it is not appropriate to start patients empirically on targeted therapy without testing for specific targets. The gene mutations, rearrangements, and fusions discussed, do not overlap with one another, and those without the genetic variant are unlikely to respond sufficiently to the targeted therapy. Therefore, it is important to discover which genetic alteration is present prior to initiating therapy. In L.L.'s case, she has clinical predictors of multiple aberrations: female, nonsmoker, and adenocarcinoma. In this case, and all cases of advanced or metastatic nonsquamous cell NSCLC, molecular testing is recommended to identify if genomic variants are present.[59] Molecular testing should be considered for patients with squamous cell histology, especially if the patient never smoked. Although the genetic alterations are almost exclusively seen in adenocarcinoma, patients with squamous cell histology may actually have a mixed histology and can therefore harbor a genetic alteration.

In addition to testing for genetic variants, evaluation of immune biomarkers is also recommended for patients with metastatic NSCLC of all histologies. Programmed death-ligand 1 (PD-L1) expression is reported as a tumor proportion score (TPS), which serves as a guide for selection of immune checkpoint inhibitor therapy. Immune checkpoint inhibitors are not recommended as first-line therapy if the patient harbors an actionable genetic alteration (eg, *EGFR, ALK, BRAF*).[49,60]

Case 98-2, Question 3: L.L. was started on erlotinib therapy based on a positive *EGFR* mutation and, within 12 months of initiation, had experienced disease progression. Would L.L. benefit from a different *EGFR*-targeted therapy?

Based on the phase-3 FLAURA trial, osimertinib is the preferred first-line *EGFR* tyrosine kinase inhibitor as it was shown to significantly improve progression-free survival compared to erlotinib and gefitinib.[61] Despite the recommendation that osimertinib be prescribed preferentially over other *EGFR* tyrosine kinase inhibitors, agents such as erlotinib are often used first line because of cost.[62] Generally, patients treated with erlotinib, gefitinib, afatinib, or dacomitinib as a first-line agent will experience disease progression after 9 to 14 months of therapy.[47,63-65] The most common reason for progression is an acquired point mutation known as *EGFR* T790M. This acquired mutation accounts for about 60% of disease progression.[66] Testing for T790M is therefore recommended for patients that progress while receiving erlotinib, gefitinib, afatinib, or dacomitinib.[59] Patients that harbor the T790M mutation may be switched to osimertinib as it targets this mutation and has been shown to improve progression-free survival in patients with T790M-positive NSCLC compared to standard chemotherapy.[67] Patients that do not test positive for T790M may receive platinum-based chemotherapy or may continue on the current *EGFR* tyrosine kinase inhibitor depending on symptoms and location of disease. As described, some patients may experience a disease flare when the tyrosine kinase inhibitor is discontinued. If this occurs, therapy should be reinitiated.[50] In the case of L.L., she should be tested for T790M and switched to osimertinib if the test comes back positive.

Case 98-2, Question 4: If L.L.'s tumor was classified as having wild-type *EGFR* and a PD-L1 TPS of 0% instead, what treatment should L.L. receive?

If the biopsy results had shown that the tumor *EGFR* was wild-type (ie, no mutation) and the tumor did not express PD-L1, L.L. would be

considered for carboplatin or cisplatin plus pemetrexed plus pembrolizumab, as shown in Table 98-6. KEYNOTE-186 evaluated the addition of pembrolizumab or placebo to carboplatin or cisplatin plus pemetrexed in patients newly diagnosed with advanced nonsquamous cell NSCLC. Randomization in this trial was stratified according to TPS of <1% versus ≥1%. Results revealed a statistically significant improvement in both disease-free and overall survival with the addition of pembrolizumab to platinum-based chemotherapy. The improvement in overall survival was consistent in all TPS groups including those with a score <1%.[68] Similarly, KEYNOTE-407 demonstrated an improvement in overall survival when pembrolizumab was added to carboplatin with either paclitaxel or *nab*-paclitaxel in patients newly diagnosed with advanced squamous cell NSCLC. Again, the improvement was seen across all tumor propensity score groups.[69]

Therefore, if L.L.'s tumor had been wild-type for *EGFR* and did not express PD-L1, she could receive cisplatin or carboplatin with pemetrexed and pembrolizumab as first-line treatment because her disease is adenocarcinoma. If she responds or has stable disease following four to six cycles of therapy, she should receive maintenance therapy with pemetrexed and pembrolizumab based on the KEYNOTE-186 trial.[68]

Case 98-2, Question 5: As discussed in Chapter 94, Adverse Effects of Chemotherapy, Immunotherapy, and Targeted Agents, the adverse effect profiles for cisplatin and carboplatin differ from each other. If a platinum-based regimen had been selected instead of targeted therapy for L.L., what characteristics about L.L. could be used to guide the selection of carboplatin versus cisplatin?

Cisplatin is predominantly associated with ototoxicity, nephrotoxicity, and neurotoxicity, whereas carboplatin is predominantly associated with myelosuppression. This would be her first cycle of chemotherapy; therefore, she is not expected to have depleted reserves of myeloid progenitor cells. Her estimated creatinine clearance is 48 mL/minute and, based on this, would be

considered to have moderate renal impairment. In this case, carboplatin may be preferred over cisplatin because it is associated with less renal toxicity and it is dosed according to the Calvert formula, which accounts for renal function:

$$\text{Total carboplatin dose (mg)} = \text{AUC}\,(\text{GFR} + 25) \quad \textbf{(Eq. 98-1)}$$

where AUC is the area under the concentration–time curve and GFR is glomerular filtration rate.[70] A typical dose of carboplatin in this setting would be determined based on an AUC to account for renal function instead of the typical weight (or m^2)-based dosing. The AUC targets are commonly 4 to 6 mg/mL × minute for most doublet regimens. If a patient with moderate renal function were to receive a fixed dose that is similar to that given to a patient with normal renal function, then systemic exposure would be higher. This higher exposure could result in greater toxicity, notably greater myelosuppression. By dosing the drug according to the patient's renal function, the risk for overdosing a patient with decreased renal function is minimized. For example, if L.L.'s carboplatin dose is ordered as AUC 5 mg/mL × minute, then her dose would be calculated as dose = 5 mg/mL × minute (48 mL/min + 25), which is 365 mg. In contrast, if her renal function were within normal range for estimated creatinine clearance (eg, 100 mL/minute), her carboplatin dose would be 625 mg (~70% higher). Several different methods may be used to estimate renal function, such as the Cockcroft and Gault equation, and the dose calculations will differ according to the method chosen. Usually, the choice of method is institution-specific, because there is no evidence to show that one estimation method is superior to the other. By consistently using the same formula, providers reduce variability in systemic exposure and thus increase the predictability of tolerance to the drug. If the patient's GFR is estimated based on serum creatinine measurements by the isotope dilution mass spectrometry method, then the GFR should be capped to a maximum of 125 mL/minute, because serum creatinine values can be underestimated when they fall below 0.7 mg/mL, as can happen in some patients. The FDA issued this safety alert to avoid

administration of high doses to patients with normal renal function and thus likely avoiding drug-related toxicity.[71]

In conclusion, if L.L.'s tumor had contained wild-type *EGFR* (instead of mutant) and did not overexpress PD-L1, then a platinum-based doublet (ie, cisplatin or carboplatin) with pemetrexed and pembrolizumab would be recommended. She has moderate renal impairment; therefore, an agent such as cisplatin would not be favored because it is associated with a high incidence of renal toxicity. Carboplatin would be a safer choice because the dose would be selected based on her renal function and is associated with a lower incidence of renal toxicity than cisplatin.

Case 98-2, Question 6: While receiving carboplatin with pemetrexed and pembrolizumab, L.L. experienced minor grade diarrhea and skin rash but otherwise tolerated treatment very well without any impact on her daily activities and quality of life. L.L. completed four cycles of chemotherapy, and she achieved a partial response. The plan is to switch to maintenance therapy. What types of side effects should L.L. be monitored for while receiving pembrolizumab maintenance?

In general, therapy with immune checkpoint inhibitors is well tolerated, especially relative to cytotoxic chemotherapy. The immune checkpoint inhibitors used to manage NSCLC block the interaction of programmed death ligands with the programmed death 1 receptor on activated T cells. This enhances the function of T cells allowing for an improved anti-tumor immune response, ultimately leading to decreased tumor growth. However, this ramping up of the immune system can cause a host of immune-related adverse reactions, some of which can be life-threatening. Pharmacists and other health care providers need to be aware of these reactions as well as how to recognize and manage them. Patients also need to be educated on the signs and symptoms of immune-related events so that treatment can be initiated promptly.

The exact incidence of immune-related adverse events is unknown. Events of any severity may occur in as many as 90% of patients, whereas reactions requiring discontinuation of therapy are

estimated to occur in 0.5% to 13% of patients.[72] Immune-mediated adverse reactions may occur in the skin or within organs and organ systems. Dermatologic reactions often occur earliest in the treatment course and can range from mild rash to a life-threatening exfoliative, ulcerated rash. Immune-mediated colitis presents as diarrhea that is graded according to number of stools per day. Liver (immune-mediated hepatitis), lung (immune-mediated pneumonitis), and kidney (immune-mediated nephritis) effects can also occur. Within the endocrine system, hypo- or hyperthyroidism can occur, as well as adrenalitis, hypophysitis, and new-onset type-1 diabetes mellitus. Neurologically, patients may present with immune-mediated encephalitis.[72]

Management of immune-related adverse events will depend on the severity as graded by the Common Terminology for Adverse Events that rates the reaction on a scale of 1 to 5, where 1 is a mild reaction and 5 is death from the adverse event.[73] Detailed information on managing these reactions can be found in the prescribing information for each individual agent. In general, therapy should be held in the event of a grade 2 toxicity. Low-dose corticosteroids (prednisone 0.5–1 mg/kg/day) can be given if the reaction lasts more than 1 week. In addition to interrupting therapy, higher dose corticosteroids (prednisone 1–2 mg/kg/day) should be given for any grade 3 or 4 events. Steroids will be slowly tapered off once the reaction returns to grade 1 or less.[72]

As mentioned earlier, NSCLC is primarily a disease in those older than 60 years. L.L. is 85 years old, and there is concern that patients, particularly older than age 80 years, may not tolerate cytotoxic chemotherapy as well as younger patients do. Hence, elderly patients are often undertreated. However, recent studies suggest that survival benefits are greater in elderly patients who receive doublet therapy versus a single agent.[74] More studies of various regimens are needed that would focus on the treatment of elderly patients, particularly effects on survival, quality of life, and tolerability. Such studies would investigate the best clinical parameters that enable prediction of response and tolerability to therapies, and also the doses associated with the best outcomes.

Because the majority of patients do not harbor actionable genetic variants, cytotoxic chemotherapy with or without immune checkpoint blockade is first line. Therefore, considerations must be given to patient's preferences, comorbidities, and performance status. It is not uncommon for those with advanced age to live alone. Caretakers who could help the patient monitor for and treat adverse effects of chemotherapy (dehydration from diarrhea or vomiting, febrile neutropenia, etc) would be an essential consideration, particularly in this population. Even though L.L. is able to continue treatment at this time, most patients eventually exhibit progressive disease. At this point, the patient would be transitioned to another cytotoxic agent with activity in NSCLC such as docetaxel or a targeted therapy like bevacizumab. An immune checkpoint inhibitor may also be used in this setting if this class of drugs have not already been administered.[75-78]

Small-Cell Lung Cancer

Epidemiology

SCLC accounts for ~13% of all lung cancer histology and affects both sexes in equal distribution. The disease is more highly attributable to smoking than NSCLC. As the number of people who smoke have decreased in the United States since its peak in the 1960s, the incidence of SCLC has also declined.[79] Relative to NSCLC, these tumors generally have a more rapid doubling time, a higher growth fraction, and early development of widespread metastases. As a consequence, SCLC is highly sensitive to chemotherapy and radiotherapy; however, most patients eventually die from recurrent disease.[80,81]

PATHOPHYSIOLOGY

SCLC is a malignancy thought to be derived from neuroendocrine cells in the bronchus and is readily diagnosed on small specimens such as bronchoscopic biopsies, fine-needle aspirates, core biopsies, and cytology. As the name suggests, these tumors consist

of small cells that may be round, oval, or spindle-shaped, with limited volume of cytoplasm, poorly defined cell borders, and finely granular chromatin.[82]

CLINICAL PRESENTATION

Most SCLCs arise centrally and present as a large hilar mass with bulky mediastinal lymphadenopathy that can cause cough and dyspnea. Rarely, patients diagnosed with SCLC present with the primary tumor located in the lung periphery, as can be the case with adenocarcinoma NSCLC. Because of smoking, patients with lung cancer may have had previously existing symptoms such as cough and dyspnea that are related to the presence of other smoking-related diseases such as COPD. Therefore, these symptoms may not prompt patients to seek medical attention quickly.[83]

DIAGNOSIS AND OVERVIEW OF TREATMENT

In general, diagnostic procedures are similar to those used to diagnose NSCLC. Staging of SCLC is used to determine prognosis and treatment. The median overall survival for patients with limited-stage disease ranges from 17 to 26 months and for extensive stage ranges from 3 to 12 months.[83] (These data were collected from an analysis of 14 studies of SCLC, and thus wide ranges for survival are reported.) Surgery (eg, thoracotomy) is appropriate for <5% of patients with early-stage disease, mainly because of the tendency for these tumors to be bulky and to metastasize quickly. Both the AJCC TNM staging system and the Veterans Administration (VA) Lung Study Group staging system are used to stage SCLC. The VA Lung Study Group uses a two-stage system, dividing patients into either limited-stage or extensive-stage disease.[84] Limited-stage disease is defined as disease confined to the ipsilateral hemithorax and encompassed in a tolerable radiation field, and extensive disease is defined as disease beyond the ipsilateral hemithorax including malignant pleural effusions or hematogenous metastases.[85,86] Limited-stage SCLC corresponds to the TNM stages I through III, whereas extensive-stage disease encompasses stage

IV.[87] As discussed subsequently, patients with limited-stage disease are treated with a combined-modality approach (ie, chemotherapy and radiation), and extensive-stage is treated with chemotherapy combined with immunotherapy. Approximately 30% of patients present with limited-stage and the rest with extensive-stage disease.[88]

CLINICAL PRESENTATION AND PATHOPHYSIOLOGY OF SMALL-CELL LUNG CANCER

CASE 98-3

QUESTION 1: M.W. is a 63-year-old female who presented to her primary doctor with heartburn and pain in the right side of her upper abdomen; she also had a feeling of gas in the stomach. In addition, she noticed a 20-pounds (9.07-kg) weight loss within 3 months, although she attributed this to changes in her diet did not present with a cough. There was no shortness of breath. The evaluation with chest radiography demonstrated the presence of a large mass in the right perihilar region with extension to the mediastinum and significant mediastinal adenopathy with narrowing of the trachea and its displacement to the left by the mass. The follow-up PET–CT scan confirmed presence of a large mass and no other areas of abnormality within the abdomen or pelvis. The patient also had a brain MRI that showed no evidence of metastatic disease. After that, the patient had a bronchoscopic evaluation and a biopsy of the mediastinal mass. Pathology came back positive for small-cell lung carcinoma. Having disease only limited to the chest and mediastinum, the patient was diagnosed with limited-stage SCLC. Peripheral blood chemistry, lactate dehydrogenase (LDH), and counts were normal.

What features of M.W.'s disease are suggestive for SCLC?

M.W.'s chief problems were heartburn and pain in the upper right side of her abdomen, not necessarily common symptoms of SCLC. Location of the tumor is a determining factor in specific symptoms that a patient can experience and can serve as an indicator of the invasiveness of the disease. Although M.W. did not present with a cough, her presentation is representative of patients diagnosed with this disease in that the tumor was centrally located with spread to the mediastinum. She also experienced weight loss, and although she attributed this to her diet, it is a symptom experienced by patients

with rapidly growing disease and associated with appetite suppression.

M.W. did not experience all of the symptoms that are frequently found in patients. Fatigue, especially together with decreased physical activity, is a common problem as well as hemoptysis.[89] Owing to the central location of most of these tumors, ~10% of patients can experience superior vena cava syndrome (SVCS). This is a very serious complication and requires immediate medical attention as a result of the growing tumor impinging upon the superior vena cava. This can restrict blood return to the heart, resulting in head and facial swelling.[90,91]

Case 98-3, Question 2: What potential complications might patients such as M.W. experience during the course of their disease?

Patients with SCLC frequently experience paraneoplastic syndromes as a result of their disease, and these often differ from patients who have NSCLC. For example, patients with NSCLC have a higher tendency to develop hypertrophic pulmonary osteoarthropathy and hypercalcemia. On the other hand, patients with SCLC have higher incidence rates for hyponatremia, Cushing syndrome, and neurologic paraneoplastic syndrome. The serum concentrations of antidiuretic hormone are often elevated in SCLC, but few of these cases fulfill the criteria for syndrome of inappropriate antidiuretic hormone secretion (SIADH) and are mostly asymptomatic. In some cases, ectopic production of atrial natriuretic factor contributes to the disorder in sodium homeostasis. Because SCLC is usually responsive to cytotoxic agents, the treatment of choice for hyponatremia is chemotherapy. If further management is needed (ie, if the cancer is nonresponsive to chemotherapy or symptomatic), fluid restriction, intravenous hypertonic saline, and treatment with demeclocycline are options, depending on severity.[1] The serum concentrations of adrenocorticotropic hormone are elevated in approximately half of patients with lung cancer, but Cushing syndrome develops in only 5% of those with SCLC. Both

low serum sodium and Cushing syndrome are poor prognostic indicators for the disease.[92]

Unlike M.W., most patients already have metastatic disease at diagnosis, and the most common sites include bone, liver, adrenal glands, and brain. Patients with hepatic and adrenal lesions do not usually experience symptoms, even if they have elevations of bilirubin, alkaline phosphatase, or hepatic transaminases.[93] In contrast, brain metastases are symptomatic in >90% of cases, and patients can often present with central nervous system complications (eg, seizures) as the first sign of the disease.[1]

CASE 98-3, QUESTION 3: M.W. reads about various treatments for her disease online. What is the utility for each of the four treatment modalities (ie, surgery, radiation, chemotherapy, and immunotherapy) for the treatment of her disease?

TREATMENT MODALITIES FOR SMALL-CELL LUNG CANCER

Surgery

As mentioned, surgery has a very limited role as part of the treatment for patients with SCLC. In general, patients with tumors larger than 3 to 7 cm and presence of any disease in the lymph nodes or distant metastases do not benefit from surgery.[94] The percentage of patients who fit this category is <5%. If surgery is chosen, the procedure usually includes lobectomy with mediastinal nodal dissection and sampling. Thereafter, patients would receive adjuvant radiation and chemotherapy and then prophylactic cranial irradiation as described in the subsequent sections.

Radiation

SCLC is responsive to radiation therapy; therefore, it is useful in treating patients with limited-stage disease. Radiation is usually given as fractionated doses over the course of 3 to 7 weeks, and total dosage targets range between 45 and 70 Gy. The optimal dose and frequency of administration of radiation is still under investigation. Improved radiation techniques deliver optimal doses of radiation to malignant sites while minimizing the impact on normal

tissue. Example techniques include intensity-modulated radiation therapy, image-guided radiation therapy, and PET–CT simulation, among others.[95-98] In addition to their cytotoxic effects, many chemotherapeutic agents also sensitize tumors to radiation. Hence, radiotherapy should start concurrently with chemotherapy, usually at the first or second cycle for limited-stage disease. Because of the high incidence of metastases to the brain (ie, >50% of patients with SCLC), prophylactic cranial irradiation consisting of 25 Gy given for 10 fractions is the standard treatment for patients with limited-stage and extensive-stage disease after completion of initial chemotherapy or chemoradiation and minimal residual systemic disease.[99,100]

Chemotherapy

The proliferative indices for SCLC cells are high and early metastatic spread is common. Therefore, systemic chemotherapy is the treatment of choice for its utility in treating metastases and because it is effective for tumor cells progressing through the cell cycle. In general, most of the regimens are platinum-based doublets with etoposide, as outlined in **Table 98-7**.[97,101,102] Immunotherapy (see next section) is added to platinum-based chemotherapy for patients with extensive-stage disease, while limited-stage patients are managed with platinum-based doublets alone.[103,104] If a response is observed, the benefit is usually seen early in the treatment course. Prolongation of treatment beyond four cycles is usually not recommended for patients with limited-stage disease because the maximum effect of the treatment is achieved in this period. Depending on response and tolerability, patients with extensive-stage disease may receive up to six cycles of primary therapy. Further, toxicity after treatment with these agents accumulates and diminishes the overall benefit to the patient beyond six courses.[105,106] Hence, treatment is usually stopped after four to six cycles and the patient is closely monitored for recurrence of the disease. Patients with extensive-stage disease treated with a platinum-based regimen with immunotherapy will receive immunotherapy maintenance until disease progression (see next section).[103,104]

Table 98-7
Representative Chemotherapy Regimens for Small-Cell Lung Cancer

Regimen	Schedule	Maintenance
Limited-Stage SCLC		
Cisplatin, day 1 Etoposide, days 1–3	Every 21 days for four cycles[97,101]	None
Carboplatin, day 1 Etoposide, days 1–3	Every 21 days for four cycles[102]	None
Extensive-Stage SCLC		
Cisplatin, day 1 Etoposide, days 1–3 Atezolizumab, day 1	Every 21 days for four to six cycles[103]	Atezolizumab, day 1, then every 21 days until disease progression
Carboplatin, day 1 Etoposide, days 1–3 Durvalumab, day 1	Every 21 days for four to six cycles[104]	Durvalumab, day 1, then every 28 days until disease progression
Cisplatin, day 1 Etoposide, days 1–3 Durvalumab, day 1	Every 21 days for four to six cycles[104]	Durvalumab, day 1, then every 28 days until disease progression
Chemotherapy for Relapsed Disease		
Preferred regimens if relapse occurs ≤6 months after first line and PS 0–2: topotecan (oral or IV), lurbinectedin, clinical trial		
Other regimens if relapse occurs ≤6 months after first line and PS 0–2: nivolumab, pembrolizumab, paclitaxel, docetaxel, irinotecan, oral etoposide, temozolomide, cyclophosphamide/doxorubicin/vincristine (CAV), gemcitabine, vinorelbine, or bendamustine		
If relapse occurs >6 months: original regimen		

PS, performance status; SCLC, small-cell lung cancer.

Immunotherapy

Because SCLC has such a proliferation rate, it also has a high mutation rate that makes the tumor cells sensitive to immune-based therapies. The addition of immune checkpoint inhibitors to first-line platinum-based doublets is the standard of care for patients diagnosed with extensive-stage disease. Clinical trials have demonstrated an improvement in progression-free and overall survival with the addition of immunotherapy.[103,104] This represents the first major advance in the management of SCLC in ~20 years.

Subsequent therapy

As mentioned, SCLC has a very high rate of recurrence; therefore, second-line therapy is usually implemented. Several choices of agents are available as shown in Table 98-7, and the selection is dependent on the overall condition of the patient (eg, performance status, toxicity from previous regimen) and the length of time after the first-line regimen was completed. Many of these agents are given as single-agent therapy except for the CAV regimen. In general, a recurrence that occurs within 6 months of treatment with first-line therapy is considered resistant and other agents are selected. If recurrence occurs after 6 months, then the same agents used for the first-line regimen may be used again.

In conclusion, M.W. would not be a good candidate for surgical removal based on the size of the primary tumor. Small-cell lung tumor cells proliferate rapidly; therefore, they are usually responsive to chemotherapy and radiation treatment. This systemic therapy would also be favored because the tumor tends to metastasize quickly and it provides a way to eradicate disease that may have spread.

Case 98-3, Question 4: M.W. begins therapy with intravenous cisplatin on day 1 combined with etoposide on days 1 to 3 given in a 21-day cycle. Four cycles are planned, and she will also receive concurrent radiation. For M.W., what is the goal of therapy? What objective baseline data should be acquired prior to starting treatment? What monitoring parameters should be utilized?

TREATMENT WITH CHEMOTHERAPY AND RADIATION

The goal of therapy for a patient with limited-stage disease such as M.W. would be to increase overall survival and achieve a potential cure. In patients with limited-stage disease, response rates of 70% to 90% are expected after a regimen such as the one M.W. is receiving, whereas response rates of 60% to 70% are expected for patients with extensive-stage disease.[97,102-104] If M.W. had been diagnosed with extensive-stage disease, then the goals would have been to increase overall survival and for palliation of symptoms. Given the complications that can arise as a result of SCLC, treatment could be used to minimize these adverse events. For example, radiotherapy is often used in treating patients with SVCS because it would reduce tumor size and enable resumption of more normal blood flow. Therefore, if a patient has acceptable performance status (eg, 0–2) and minimal to no comorbidities, then treatment such as the one that M.W. is receiving is the best course of action.

A treatment regimen such as cisplatin and etoposide plus radiation is tolerated by most patients, especially because the number of cycles is limited to four. However, administration of these cytotoxic agents is associated with several adverse effects, some of which can be life-threatening. Hence, the clinician is expected to anticipate these events and plan treatment accordingly to minimize complications. The patient is receiving cisplatin, which causes several different adverse effects such as renal insufficiency, sensory neuropathy, and ototoxicity and is considered highly emetogenic (refer to Chapter 94, Adverse Effects of Chemotherapy, Immunotherapy, and Targeted Agents). Hydration and diuresis are required with cisplatin doses >40 mg/m^2 to maintain a urine output of 100 to 150 mL/hour before administration of the drug. The intravenous fluids are often supplemented with potassium and magnesium to counteract electrolyte wasting from cisplatin. Monitoring of serum creatinine, electrolytes including magnesium and calcium, is performed usually before each infusion of chemotherapeutics. An appropriate antiemetic regimen must be implemented to prevent both acute and delayed nausea and

vomiting. For etoposide, neutropenia is usually the dose-limiting toxicity. Therefore, monitoring of absolute neutrophil count (ANC) is important, and if the counts do not recover before the next dose is due, then delays in treatment or dosage reductions occur. In phase-III clinical trials for this regimen, grade 4 leukopenia occurred in ~35% to 40% of patients, and any grade fever and infection in >20%.[96,97] Therefore, consideration must be given toward the use of colony-stimulating factors to manage this latter event after radiation is completed (refer to Chapter 94, Adverse Effects of Chemotherapy and Targeted Agents).

In conclusion, the goal of M.W.'s therapy is a potential cure. Hydration with fluids supplemented with potassium and magnesium must be initiated prior to cisplatin therapy to prevent cisplatin-induced renal toxicity. During therapy, clinicians must observe for decreased ANC because of etoposide and may need to implement delays in therapy or use of a colony-stimulating factor (eg, granulocyte colony–stimulating factor, filgrastim, or pegfilgrastim). Supportive care such as antiemetics during therapy to prevent or manage cisplatin-associated acute- and delayed-phase nausea and vomiting will also be essential.

CASE 98-3, QUESTION 5: M.W. tolerated therapy very well with mild esophagitis and cough during treatment. She did not experience any vomiting because of aggressive antiemetic use, nor did she exhibit any neuropathy or hearing loss. What adverse conditions that M.W. experienced are associated with her treatment?

Both esophagitis and cough are likely attributable to radiation effects. If esophagitis worsens to grade 3 or more, patients can lose the ability to swallow and may require a feeding tube. During therapy, cough can develop and patients may become concerned that it is a sign of worsening disease. Radiation-induced pneumonitis, acute (in first 3 months) and chronic (4–12 months), can be a frequent cause of the new onset of cough, which can be ameliorated with corticosteroid treatment.

Case 98-3, Question 6: After two cycles of chemotherapy with concurrent radiotherapy, a CT scan indicates a partial response. Therefore, an additional two cycles of cisplatin and etoposide were planned. How is the course of M.W.'s disease likely to proceed?

The chances for long-term survival >5 years are very low, even for the patient with no other comorbidities and limited-stage disease such as M.W. At the completion of chemotherapy, M.W. should be offered therapy with prophylactic cranial irradiation because brain metastases occur in >50% of patients with SCLC. Prophylactic cranial irradiation not only reduces the incidence of metastatic disease but also increases overall survival.[99] Within a year of completing therapy, most patients experience progressive or relapsed disease. The duration of the remission is the single largest predictor of outcome and patients are classified as having either sensitive or refractory disease, depending on length of this duration. Approximately half of those tumors that are deemed sensitive in this setting will respond to second-line therapy.[106] Therefore, most SCLC tumors become resistant to therapy either during first-line or salvage therapy. Patients can also exhibit second primary tumors, especially NSCLC, during the course of the disease.

ACKNOWLEDGMENT

99

Colorectal Cancer

Marlo Blazer and Joshua Reardon

CORE PRINCIPLES		CHAPTER CASES
1	Family history, patient-specific factors, and environmental factors are identified as risk factors for colorectal cancer (CRC). Environmental factors could be modified to reduce the risk of CRC.	**Case 99-1 (Question 1)**
2	Early detection of CRC through screening reduces cancer-related mortality. Most patients at average risk of CRC are recommended to begin screening at age 45 years.	**Case 99-1 (Question 2)**
3	Patients may be asymptomatic at diagnosis or have nonspecific symptoms. Carcinoembryonic antigen may be elevated in patients with CRC, but it cannot be used alone for diagnosis.	**Case 99-2 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
4	Adjuvant combination chemotherapy with fluorouracil and oxaliplatin is currently considered the standard of care for patients with stage III CRC after surgery with curative intent.	**Case 99-2 (Questions 2, 3)**
5	All patients diagnosed with localized CRC should undergo routine surveillance visits with their oncologist for a period of 5 years after completion of their definitive therapy.	**Case 99-2 (Question 5)**
6	During the last decade, newer chemotherapy agents (oxaliplatin, irinotecan) and targeted therapies (bevacizumab, ramucirumab, ziv-aflibercept, cetuximab, panitumumab, regorafenib) have increased the overall survival of patients with metastatic CRC. Fluoropyrimidines (fluorouracil or capecitabine) remain the backbone of therapy in the first- and second-line treatment of advanced cancer. The right combination and sequencing of these agents are vital to improving the care of patients with CRC.	**Case 99-3 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
7	Use of specific predictive markers helps maximize the desired outcome in metastatic CRC. Patients with *RAS* mutant tumors do not derive any benefit from anti–epidermal growth factor receptor (EGFR) monoclonal antibody therapy. Tumor sidedness (right- vs left side) further assists in selecting candidates for anti-EGFR therapy in the front-line setting.	**Case 99-3 (Question 4)**
8	Myelosuppression, diarrhea, and peripheral neuropathy are potential dose-limiting toxicities associated with chemotherapy agents used in the treatment of colon and rectal cancers. Prevention strategies, diligent monitoring, and adequate supportive-care measures are vital to effective toxicity management and should be used to maintain patient safety and enhance the quality of life.	**Case 99-2 (Questions 3, 4) Case 99-3 (Question 3)**

CORE PRINCIPLES		CHAPTER CASES
9	Severe, life-threatening adverse effects are uncommon, but potential hazards are associated with targeted CRC therapies, and avoiding their use is warranted in patients at increased risk of experiencing these complications. Prevention and treatment strategies are available for common adverse effects such as hypertension associated with vascular endothelial growth factor therapy or EGFR inhibitor–induced dermatologic toxicity.	**Case 99-3 (Questions 3, 5, 6)**
10	Certain genetic variants of key enzymes involved in the catabolism of fluorouracil and irinotecan are associated with increased toxicity from these agents. The clinical utility of identifying these variants in an effort to avoid or manage these toxicities continues to be elucidated.	**Case 99-3 (Question 2)**

INTRODUCTION

Epidemiology, Etiology, and Pathophysiology

Colorectal cancer (CRC) is the malignant growth of tumor that begins from the inner wall of the colon or rectum. It is the fourth most commonly diagnosed cancer in the United States as well as the fourth leading cause of cancer-related deaths.[1] In 2020, it was estimated that there would be 147,950 new cases of CRC with a

median age at diagnosis of 67 years, and an estimated 53,200 people would die of this disease.[1] During the last two decades, new agents, better predictive markers, and more personalized treatment have enabled improvement in the detection, safety, and survival of patients with CRC. The age-adjusted 5-year relative survival rate in 1980 was 51.4% and is estimated to be 64.6% in 2020 (based on data from SEER 18, years: 2010–2016).[1]

The formation of CRC is a multistep process. It begins with an abnormal growth of tissue known as a polyp (adenoma) originating from the innermost wall of the colon. The process of transformation from a polyp to malignant disease can take up to 10 to 15 years.[2] The vast majority of colon and rectal cancers are classified as adenocarcinomas, meaning that they arise from the glandular tissue responsible for producing the secretions of the gastrointestinal (GI) tract. Approximately two-thirds of these cancers will arise from the colon, and the remainder will form in the rectum. CRC is among the few cancers that can be prevented by the removal of precancerous tissue; therefore, early detection is crucial.

The etiology of CRC is complex, involving patient-specific, environmental, and genetic factors. Of these, age is considered the most important risk because >90% of patients diagnosed are older than 50 years of age.[3] Other patient-specific risk factors are family history of colon cancer, history of previous colonic polyps, and inflammatory bowel disease (ulcerative colitis or Crohn disease). Environmental factors like a diet consisting primarily of red meat, high fat, and low fiber can also increase the risk of CRC, as can a sedentary lifestyle, obesity, excessive alcohol consumption, and long-term smoking.[4,5] Smoking, particularly early in life, has been shown to increase the risk of developing CRC. Patients who smoked more than 12 pack-years of cigarettes before age 30 are at increased risk of recurrence after a diagnosis of stage III colon cancer.[4]

Hereditary syndromes account for 6% to 10% of all CRCs, and in up to 20% of patients diagnosed before age 50.[6] Specific inherited syndromes include hereditary nonpolyposis colon cancer, also known as Lynch syndrome, and familial adenomatous polyposis

(FAP). Although accounting for <1% of all CRC cases, FAP is associated with a lifetime risk of CRC of >90% because of an autosomal dominant germ line mutation causing the development of dozens to thousands of polyps distributed in the colon and rectum, usually beginning in adolescence.[7] Lynch syndrome accounts for 2% to 3% of CRCs.[7] It is an autosomal dominant disorder that also has an early age of onset (age 20–25 years) and is associated with an increased risk of other cancers, such as endometrial cancer, cancers of the urinary tract, small intestine, ovary, stomach, pancreas, biliary tract, brain, and skin. Screening for both of these inherited syndromes begins at an early age (age 10–15 years for FAP and age 20–25 for Lynch syndrome).[6]

Clinical Presentation and Diagnosis

Symptoms associated with the development of colon and rectal cancers are often subtle and can mimic “generalized” symptoms associated with numerous other benign conditions, such as abdominal pain, constipation, diarrhea, bloating, rectal bleeding, and other sudden changes in bowel habits or caliber. Unintentional weight loss, anemia, and weakness may also be present, particularly in advanced stages of the disease. A diagnosis is made once a colonoscopy or sigmoidoscopy is performed, and a biopsy is obtained to confirm the presence of cancer. Additional diagnostic procedures would be performed before initiating treatment, including a computed tomography (CT) scan of the chest, abdomen, and pelvis as well as laboratory collection of blood to obtain a baseline carcinoembryonic antigen (CEA) level. These determine the extent of the disease and provide a means to monitor for recurrence or progression after or on treatment. For cancers of the rectum, an endoscopic ultrasound may also be performed to aid in the preoperative or clinical staging of the tumor. Definitive or pathologic staging for all tumors of the colon and rectum takes place during surgical resection.

Treatment Overview

The therapeutic modalities available to the patient with CRC are similar to those used in other solid tumors. Surgery, radiation, and chemotherapy all have roles in both localized and advanced disease, but how each of these strategies is used, and sequencing, depends on the location and extent of the disease and on the goal of therapy. Stage of disease at diagnosis determines the initial treatment. CRC, like other solid tumors, uses the TNM staging system, but it is unique in that it is the depth of invasion of the primary tumor and not its size that determines the "T" in the TNM staging. Like other solid tumors, the remaining components of this classification system are lymph node involvement (N) and metastatic spread (M). Colon and rectal cancers are staged in the exact same manner; however, rectal tumors lie in closer proximity to the anal sphincter; therefore, the risk of localized treatment failure and of recurrence at the initial site of disease is increased. In general, surgery is used as the primary initial modality for patients with stages I, II, and III disease. It may also be employed in selected patients with metastatic stage IV disease at some point during their treatment course. Radiation is usually reserved for patients with rectal cancer. This chapter will primarily focus on the use of systemic therapy (ie, chemotherapy and targeted therapy) for patients diagnosed with colon and rectal cancer.

Etiology

CASE 99-1

Question 1: O.B., a 35-year-old female, recently learned that her 53-year-old father was diagnosed with colon cancer. O.B. is obese and smokes half a pack of cigarettes per day. She loves eating out and spends most of her evening watching TV at home. O.B. would like to know the risk factors for CRC.

Is there anything she can do to reduce her risk of developing CRC in the future?

O.B. is at an increased risk of developing CRC, given her family history of colon cancer. In addition, she is obese, lives a sedentary lifestyle, and smokes. She eats out, but no information is given about her diet. There are modifiable risk factors, which she could address to lower her risk of developing CRC. O.B. can lose weight through exercise and adopt a high-fiber, low-fat diet. In addition, she can stop smoking, which can help reduce the risk of colorectal as well as other cancers.

Screening

Case 99-1, Question 2: Given O.B.'s family history (her father had a colon cancer diagnosis), she has questions related to preventative actions she can take. Is there a method to detect something "pre-cancerous" (meaning, before it becomes colon cancer)? If so, at what age should O.B. start screening?

Colon and rectal cancers are among the few cancers that can be prevented by the removal of precancerous tissue; therefore, early detection is crucial. As described above, formation of CRCs is a multistep process, and the early precancerous tissue is identifiable and can be removed. CRC is not always asymptomatic, but early detection of CRC through screening has been proven to reduce mortality. A variety of screening methods exist, including fecal screening tests, stool DNA tests (such as Cologuard), digital rectal examination, barium enemas, endoscopy, and CT colonography. Fecal screening tests are designed to detect occult blood in the stool and are relatively inexpensive and noninvasive. There are two main types: the fecal occult blood test (FOBT) and the fecal immunochemical test (FIT). The FOBT has been shown to reduce mortality from CRC by 33%, but the test does require diet restrictions prior to sampling.[8] The FIT uses antibodies to detect hemoglobin or other blood components and, compared to FOBT, has no drug or food interactions. Screening guidelines acknowledge that FIT may be more sensitive than FOBT; however, neither is preferred over the other, possibly because of a lack of mortality data with FIT along with

potential cost/out-of-pocket difference between the two tests. Stool DNA tests include molecular assays for DNA mutation and methylation biomarkers associated with CRCs as well as a non-DNA immunohistochemical assay similar to what is used in FITs. In a clinical study of asymptomatic patients that were at least age 50 years (*n* = 9989), compared to the gold standard of colonoscopy, the sensitivity for detecting CRC was 92.3% with the stool DNA test and 73.8% for FIT; however, the sensitivity for detecting precancerous lesions (that can be removed as a preventative intervention) was 42.4% with the stool DNA test and 23.8% with FIT.[9] Endoscopic screening for CRC includes either flexible sigmoidoscopy or colonoscopy, and both offer the ability to remove polyps and obtain biopsy samples during the procedure. The advantages of sigmoidoscopy are that no sedation is required, a simple preparation (two Fleet enemas) is used, and it can be performed in various settings. Patients may choose flexible sigmoidoscopy over colonoscopy if they do not want to go under sedation or undergo extensive bowel preparation. Sigmoidoscopy has been shown to reduce the incidence of CRC by 33% and mortality because of CRC by 43%.[10] However, flexible sigmoidoscopy allows for examination only of the sigmoid colon and rectum, whereas colonoscopy examines the entire colon. As such, colonoscopy is the most widely accepted screening tool; it has been shown to reduce the incidence of CRC by 77% and is associated with significant risk reduction in both right- and left-sided colon cancer incidences.[11] A relatively new method known as CT colonography provides two- and three-dimensional images of the colon. As with endoscopic procedures, it requires complete bowel preparation to remove feces from the intestine. This screening technique has demonstrated an approximate 80% sensitivity to detect polyps >6 mm in size and 90% sensitivity for polyps >1 cm.[12] However, any cancerous lesion detected will ultimately necessitate an examination by colonoscopy.

CEA is a tumor marker that is detected in the blood and has been evaluated as a screening tool, but its primary use is in monitoring response to treatment and not screening. Healthy smokers are likely to have twice the CEA level compared to nonsmokers. Further,

administration of therapies given for metastatic colon cancer can cause false elevation of CEA without disease progression; so even in monitoring response to treatment, it is only used in conjunction with other modalities.

The American Cancer Society (ACS), the U.S. Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology have jointly published screening recommendations for the early detection of CRC.[13] According to them, it is a strong recommendation that screening for adults with an average risk of developing CRC should begin at the age of 50 years (**Table 99-1**). Notably, an update by the ACS does now, as a qualifying recommendation, lower the age at which screening should start to 45 years, based on the recent increase in CRC incidence in younger persons, but acknowledges that the benefit gained by screening average-risk persons between ages 45 and 49 years is currently unknown.[3] Patients at average risk of developing CRC will not have genetic predisposition or history of a family member with CRC. In addition, patients in this category will have no history of polyps, previous history of CRC, inflammatory bowel disease, chronic ulcerative colitis, or Crohn colitis.

Table 99-1

American Cancer Society Screening Recommendation for Colorectal Cancer by Age and Risk

Average risk	The ACS recommends that people at average risk[a] of colorectal cancer start regular screening at age 45. Average risk means a person does NOT have any of the following: ▪ A personal history of colorectal cancer or certain types of polyps ▪ A family history of colorectal cancer ▪ A personal history of inflammatory bowel disease (ulcerative colitis or Crohn disease) ▪ A confirmed or suspected hereditary colorectal cancer syndrome, such as familial adenomatous polyposis (FAP) or Lynch syndrome (hereditary nonpolyposis colon cancer or HNPCC)

	A personal history of getting radiation to the abdomen (belly) or pelvic area to treat a prior cancer Options for screening: Stool-based tests ▪ Fecal immunochemical test every year ▪ High-sensitivity, guaiac-based fecal occult blood test every year ▪ Multitarget stool DNA test every 3 years Structural examinations ▪ Colonoscopy every 10 years ▪ CT colonography every 5 years ▪ Flexible sigmoidoscopy every 5 years
Family history	Begin screening at age of 40 or 10 years younger from first-degree relative colorectal cancer diagnosis
Hereditary nonpolyposis colon cancer	Begin screening at age of 20–25 or 10 years younger from first-degree relative colorectal cancer diagnosis
Familial adenomatous polyposis	Begin screening at age of 10–12 years
Inflammatory bowel disease, chronic ulcerative colitis, or Crohn colitis	Begin screening at 8–15 years after diagnosis

[a]Interval of surveillance is shown for negative findings. If polyps are found at screening, interval of surveillance may change based on biopsy results.[8]

O.B. is a 35-year-old female with a first-degree relative with a diagnosis of colon cancer at age 53. It is less likely she would develop CRC through a hereditary syndrome because her father was diagnosed after age 50. She does, however, have nearly double the lifetime risk of developing CRC because a first-degree relative had CRC.[14] Because O.B.'s father had CRC diagnosed before age 60, she is at increased risk for developing the disease and should consider initiating a colorectal screening program at age 43 (or 10 years earlier than her father was diagnosed at age 53).[12]

Clinical Presentation

CASE 99-2

QUESTION 1: B.R. is a 66-year-old male who was in his usual state of health until recently when he decided to visit his general practitioner owing to progressively worsening GI symptoms, including abdominal cramping and changing bowel habits. He admits to also having some blood in his stool at times, which he attributes to his hemorrhoids. His family history is notable for a paternal uncle with gastric cancer. He occasionally drinks alcohol and has never smoked or used illicit or recreational drugs. On physical examination, he is a well-nourished, well-developed male who is afebrile, alert and oriented, and in no apparent distress. He has no palpable masses and no hepatomegaly, and his abdomen is soft and nontender with normal active bowel sounds. The rest of his review of systems is unremarkable. His performance status is excellent. He does have a history of type 2 diabetes mellitus and hypercholesterolemia, which are both controlled on his current medication regimen. Vital signs and laboratory values obtained are as follows:

Blood pressure, 108/71 mm Hg
Heart rate, 95 beats/minute
Respiratory rate, 18 breaths/minute
White blood cell (WBC) count, 4.8×10^3 cells/μL
Hemoglobin, 11.6 g/dL
Hematocrit, 35.1%
Platelet count, 208×10^3 cells/μL
Total bilirubin, 0.3 mg/dL
Serum creatinine, 0.8 mg/dL
Blood urea nitrogen, 15 mg/dL
Alkaline phosphatase, 61 IU/L
Lactate dehydrogenase, 366 IU/L
Albumin, 4.2 g/dL
Hemoglobin A1C, 6.2%

Are any of the symptoms that B.R. is exhibiting associated with CRC?

Although the symptoms B.R. is describing are nonspecific in nature, the changes in bowel habits in addition to the blood in his stools are symptoms associated with the development of CRC. Given his age, symptoms, and lack of prior cancer screening, additional workup is warranted with one of the screening modalities mentioned earlier in this chapter, preferably colonoscopy.

Chemotherapy for Localized Colorectal Cancer

ADJUVANT THERAPY

Case 99-2, Question 2: After a colonoscopy, B.R. is found to have a moderately differentiated adenocarcinoma of the colon lying 18 cm from the anal verge invading through the muscularis propria with lymphovascular invasion and involvement of 8 of 25 regional lymph nodes. A CT scan of his chest, abdomen, and pelvis shows no evidence of metastatic disease. A baseline CEA level of 8.0 ng/mL (normal range, 0–3.0 ng/mL for nonsmokers and 0–6.0 ng/mL for smokers) is reported. After surgical resection, would B.R. benefit from adjuvant chemotherapy? Which chemotherapy agents or regimen gives B.R. the best chance to avoid a future recurrence?

Historically, fluorouracil (also known as 5-fluorouracil [5-FU]), a fluoropyrimidine, combined with leucovorin was considered the standard chemotherapy for adjuvant treatment of stage III colon cancer based on studies that showed both an improvement in disease-free survival (DFS) and overall survival (OS) over no chemotherapy after surgery.[15] For patients with stage II disease, only those with certain high-risk features, defined by large (T4) tumors that were adherent to or invaded other organs, were obstructive, were poorly differentiated, had venous invasion, or in patients that experienced bowel perforation or where fewer than 10 lymph nodes were examined after curative-intent surgery appeared to gain any benefit from fluorouracil/leucovorin given after surgery.[15,16] Leucovorin stabilizes the binding of an active metabolite of fluorouracil known as fluorodeoxyuridine monophosphate to its intracellular target thymidylate synthase, ultimately enhancing the cytotoxicity of fluorouracil. Fluorouracil is administered primarily in two different ways—as a bolus injection over 3 to 5 minutes, and this is followed by a continuous infusion over 24 to 46 hours (depending on the regimen). Single-agent capecitabine, an oral prodrug of fluorouracil, offers convenient administration and is as effective as intravenous fluorouracil modulated with leucovorin.[17] At present, the combination of fluorouracil and leucovorin or capecitabine monotherapy are the preferred adjuvant regimes for stage III colon

cancer for patients that are older than age 70 because this population does not seem to benefit from the addition of other cytotoxic agents to this fluoropyrimidine backbone.[16,18]

For patients younger than age 70 years, the addition of oxaliplatin, a platinum agent, to the fluoropyrimidine backbone (either capecitabine alone or fluorouracil with leucovorin) is considered the current standard of care in the adjuvant setting for patients with stage III disease, because several landmark trials have shown the addition of oxaliplatin in this population can improve both DFS and OS over fluorouracil and leucovorin alone.[19,20] The increase in DFS and in OS with the addition of oxaliplatin was less pronounced for those patients with stage II (node-negative) disease, and so the use of oxaliplatin in this population is controversial.[16] There were several fluorouracil and oxaliplatin regimens historically used in clinical practice. However, more current practices recommend that when combining fluorouracil with additional cytotoxic agents, the infusional modality be primarily utilized rather than bolus (IV push) regimens to maximize efficacy while minimizing toxicity, although the infusional regimens do still contain a small portion of the entire fluorouracil dose given as an initial bolus injection.

As stated, oxaliplatin may also be combined with capecitabine as the fluoropyrimidine backbone. This is considered equally effective to the combination with fluorouracil modulated with leucovorin, with the main difference seen in toxicity patterns. Capecitabine is given orally typically as a twice-daily dose for 14 days of each 21-day cycle. Often the decision of which fluoropyrimidine to choose is multifactorial owing to the nuances of clinical practice. Potential factors that play a role in the agent chosen can include, but are not limited to, toxicity differences, institutional resources (ambulatory pump availability, etc.), insurance coverage, duration of adjuvant therapy (discussed later), and patient preference. Additional factors that could influence the selection of a capecitabine-based regimen include the presence of renal impairment and relevant drug–drug interactions, particularly concomitant warfarin use. Regimens that are commonly used in the adjuvant treatment of colon cancer are noted in **Table 99-2**.

Table 99-2
Selected Regimens Used in Metastatic or Advanced Colorectal Cancer

Regimen	Dosing
Oxaliplatin-Based Regimens	
mFOLFOX6[a]	▪ Oxaliplatin 85 mg/m^2 IV over 2 hours, day 1 ▪ Leucovorin 400 mg/m^2 IV over 2 hours, day 1 ▪ Fluorouracil 400 mg/m^2 IV bolus on day 1, then 1200 mg/m^2/day × 2 days (total 2400 mg/m^2 over 46–48 hours) IV continuous infusion Repeat every 2 weeks
mFOLFOX6 + bevacizumab	▪ Oxaliplatin 85 mg/m^2 IV over 2 hours, day 1 ▪ Leucovorin 400 mg/m^2 IV over 2 hours, day 1 ▪ Fluorouracil 400 mg/m^2 IV bolus on day 1, then 1200 mg/m^2/day × 2 days (total 2400 mg/m^2 over 46–48 hours) IV continuous infusion ▪ Bevacizumab 5 mg/kg IV, day 1 Repeat every 2 weeks
mFOLFOX6 + panitumumab[b]	▪ Oxaliplatin 85 mg/m^2 IV over 2 hours, day 1 ▪ Leucovorin 400 mg/m^2 IV over 2 hours, day 1 ▪ Fluorouracil 400 mg/m^2 IV bolus on day 1, then 1200 mg/m^2/day × 2 days (total 2400 mg/m^2 over 46–48 hours) IV continuous infusion ▪ Panitumumab 6 mg/kg IV over 60 minutes, day 1 Repeat every 2 weeks

Regimen	Dosing
CapeOX[a,c]	▪ Oxaliplatin 130 mg/m^2 IV over 2 hours, day 1 ▪ Capecitabine 850–1000 mg/m^2 twice daily PO for 14 days Repeat every 3 weeks
CapeOX[c] + bevacizumab	▪ Oxaliplatin 130 mg/m^2 IV over 2 hours, day 1 ▪ Capecitabine 850–1000 mg/m^2 PO twice daily for 14 days ▪ Bevacizumab 7.5 mg/kg IV, day 1 Repeat every 3 weeks
Irinotecan-Based Treatment Regimens	
FOLFIRI	▪ Irinotecan 180 mg/m^2 IV over 30–90 minutes, day 1 ▪ Leucovorin 400 mg/m^2 IV infusion to match duration of irinotecan infusion, day 1 ▪ Fluorouracil 400 mg/m^2 IV bolus day 1, then 1200 mg/m^2/day × 2 days (total 2400 mg/m^2 over 46–48 hours) continuous infusion Repeat every 2 weeks
FOLFIRI + bevacizumab	▪ Irinotecan 180 mg/m^2 IV over 30–90 minutes, day 1 ▪ Leucovorin 400 mg/m^2 IV infusion to match duration of irinotecan infusion, day 1 ▪ Fluorouracil 400 mg/m^2 IV bolus day 1, then 1200 mg/m^2/day × 2 days (total 2400 mg/m^2 over 46–48 hours) IV continuous infusion ▪ Bevacizumab 5 mg/kg IV, day 1 Repeat every 2 weeks

Regimen	Dosing
FOLFIRI + cetuximab	▪ Irinotecan 180 mg/m^2 IV over 30–90 minutes, day 1 ▪ Leucovorin 400 mg/m^2 IV infusion to match duration of irinotecan infusion, day 1 ▪ Fluorouracil 400 mg/m^2 IV bolus day 1, then 1200 mg/m^2/day × 2 days (total 2400 mg/m^2 over 46–48 hours) IV continuous infusion ▪ Repeat every 2 weeks ▪ Cetuximab 400 mg/m^2 IV over 2 hours first infusion, then 250 mg/m^2 IV over 60 minutes weekly ▪ OR ▪ Cetuximab 500 mg/m^2 IV over 2 hours, day 1, every 2 weeks
FOLFIRI + panitumumab[b]	▪ Irinotecan 180 mg/m^2 IV over 30–90 minutes, day 1 ▪ Leucovorin 400 mg/m^2 IV infusion to match duration of irinotecan infusion, day 1 ▪ Fluorouracil 400 mg/m^2 IV bolus day 1, then 1200 mg/m^2/day × 2 days (total 2400 mg/m^2 over 46–48 hours) IV continuous infusion ▪ Panitumumab 6 mg/kg IV over 60 minutes, day 1 Repeat every 2 weeks

Regimen	Dosing
FOLFIRI + ziv-aflibercept Currently approved only in the second-line setting	▪ Irinotecan 180 mg/m^2 IV over 30–90 minutes, day 1 ▪ Leucovorin 400 mg/m^2 IV infusion to match duration of irinotecan infusion, day 1 ▪ Fluorouracil 400 mg/m^2 IV bolus day 1, then 1200 mg/m^2/day × 2 days (total 2400 mg/m^2 over 46–48 hours) continuous infusion ▪ Ziv-aflibercept 4 mg/kg IV over 60 minutes Repeat every 2 weeks
FOLFIRI + ramucirumab Currently approved only in the second-line setting	▪ Irinotecan 180 mg/m^2 IV over 30–90 minutes, day 1 ▪ Leucovorin 400 mg/m^2 IV infusion to match duration of irinotecan infusion, day 1 ▪ Fluorouracil 400 mg/m^2 IV bolus day 1, then 1200 mg/m^2/day × 2 days (total 2400 mg/m^2 over 46–48 hours) continuous infusion ▪ Ramucirumab 8 mg/kg IV over 60 minutes Repeat every 2 weeks
Fluoropyrimidine Treatment Regimens	
Capecitabine[d,e] ± bevacizumab	▪ Capecitabine 850–1250 mg/m^2 PO twice daily, days 1–14 ▪ ± Bevacizumab 7.5 mg/kg IV, day 1 Repeat every 3 weeks
Bolus or infusional 5-FU/leucovorin (Roswell Park regimen)	▪ Leucovorin 500 mg/m^2 IV over 2 hours, days 1, 8, 15, 22, 29, and 36 ▪ Fluorouracil 500 mg/m^2 IV bolus 1 hour after start of leucovorin, days 1, 8, 15, 22, 29, and 36 Repeat every 8 weeks

Regimen	Dosing
Simplified biweekly infusional 5-FU/leucovorin[d,e] ± bevacizumab	▪ Leucovorin 400 mg/m^2 IV over 2 hours on day 1 ▪ Fluorouracil bolus 400 mg/m^2 IV and then 1200 mg/m^2/day × 2 days (total 2400 mg/m^2 over 46–48 hours) continuous infusion ± Bevacizumab 5 mg/kg IV on day 1
Oxaliplatin- and Irinotecan-Containing Regimens	
FOLFOXIRI ± bevacizumab	▪ Irinotecan 165 mg/m^2 IV day 1 ▪ Oxaliplatin 85 mg/m^2 day 1 ▪ Leucovorin 400 mg/m^2 day 1 ▪ Fluorouracil 1200 mg/m^2/day × 2 days (total 2400 mg/m^2 over 48 hours) continuous infusion starting on day 1 Repeat every 2 weeks ± Bevacizumab 5 mg/kg IV, day 1
Salvage Therapy	
Regorafenib Used postprogression on irinotecan, oxaliplatin, fluorouracil, and an EGFR inhibitor (if *RAS* wild-type)	160 mg PO daily in the morning with a low-fat breakfast on days 1–21. Repeat every 28 days
Trifluridine/tipiracil Used postprogression on irinotecan, oxaliplatin, fluorouracil, and an EGFR inhibitor (if *RAS* wild-type)	35 mg/m^2 orally twice daily, after morning and evening meals, on days 1–5 and days 8–12 of each 28-day cycle Dose is based on trifluridine content of combination tablets BSA was capped at 2.3 m^2 in registrational trial
Immunotherapy in Select Populations	

Regimen	Dosing
Pembrolizumab Used in first or subsequent lines of therapy for metastatic disease for tumors that are MSI-H or dMMR Used in patients with TMB-H disease as defined by ≥10 mutations/megabase postprogression on stand therapies	200 mg IV over 30 minutes every 3 weeks OR 400 mg IV over 30 minutes every 6 weeks
Nivolumab Used postprogression on irinotecan, oxaliplatin, and fluorouracil for tumors that are MSI-H or dMMR	240 mg IV over 30 minutes every 2 weeks OR 480 mg IV over 30 minutes every 4 weeks
Nivolumab + ipilimumab Used postprogression on irinotecan, oxaliplatin, and fluorouracil for tumors that are MSI-H or dMMR	Nivolumab 3 mg/kg IV over 30 minutes Ipilimumab 1 mg/kg IV over 30 minutes Both agents given over 30 minutes each for four doses followed by nivolumab alone: 240 mg IV over 30 minutes every 2 weeks OR 480 mg IV over 30 minutes every 4 weeks
***BRAF* V600E-Mutated Colorectal Cancer**	
Encorafenib + cetuximab	Encorafenib 300 mg PO daily Cetuximab 400 mg/m^2 IV over 2 hours first infusion, then 250 mg/m^2 IV over 60 minutes weekly OR Cetuximab 500 mg/m^2 IV over 2 hours, day 1, every 2 weeks
Encorafenib + panitumumab[b]	Encorafenib 300 mg PO daily Panitumumab 6 mg/kg IV over 60 minutes, day 1
HER2-Amplified Colorectal Cancer (*RAS/BRAF* Wild-Type)	
Trastuzumab + lapatinib	Trastuzumab 4 mg/kg IV loading dose × 1, followed by 2 mg/kg IV weekly Lapatinib 1000 mg PO daily
Trastuzumab + pertuzumab	Trastuzumab 8 mg/kg IV loading dose × 1, followed by 6 mg/kg IV every 3 weeks Pertuzumab 840 mg IV loading dose × 1, followed by 420 mg IV every 3 weeks

[a]Oxaliplatin combined with either fluorouracil or capecitabine (as in mFOLFOX6 or CAPEOX) for 6 months of therapy is also used in the adjuvant setting (postsurgery) for stage III colon cancer.

[b]For panitumumab, if the first infusion is tolerated, administer subsequent infusions over 30 to 60 minutes. Administer doses higher than 1000 mg over 90 minutes.

[c]Phase II data exist for biweekly regimens with oxaliplatin given at 85 mg/m^2 every 2 weeks and capecitabine given on days 1 to 7 and days 15 to 21.

[d]Fluorouracil or capecitabine with or without bevacizumab is an appropriate therapy in a poor performance status patient where concerns of the added toxicity of oxaliplatin or irinotecan outweigh benefit.

[e]Capecitabine alone or fluorouracil with leucovorin alone for 6 months of therapy are also appropriate as adjuvant therapy for patients with high-risk stage II colon cancer or as adjuvant therapy for patients older than age 70 years with stage III colon cancer postsurgery.

Irinotecan in combination with fluorouracil and leucovorin has been evaluated in the adjuvant setting for stage III colon cancer. The use of irinotecan did not produce any benefit in terms of DFS; however, toxicities were increased with the combination of irinotecan and fluorouracil versus fluorouracil alone.[21] Therefore, irinotecan is not an agent used at present time in the adjuvant setting for CRC. In addition, some of the biologics available for the treatment of metastatic colon cancer, such as bevacizumab and cetuximab, have been studied in the adjuvant setting as well. To date, none of the biologics approved for metastatic colon cancer (bevacizumab, ramucirumab, ziv-aflibercept, cetuximab, panitumumab, or regorafenib) are approved or recommended in the adjuvant setting.[19]

DURATION OF ADJUVANT THERAPY

The primary role of chemotherapy in this setting is to reduce the risk of relapse and prolong DFS by eradicating residual, undetectable disease. Historically, for stage III (ie, patients with positive lymph nodes) disease, 6 months of therapy with oxaliplatin combined with either capecitabine or infusional fluorouracil and leucovorin after surgery was the standard of care. However, in an attempt to balance the reduced risk of DFS with the risk of increased toxicity of 6 months of oxaliplatin-based therapy, namely persistent neurotoxicity,

six more recent trials evaluated the ability of 3 months of adjuvant therapy to produce the same results (ie, to be noninferior) to 6 months.[22]

A pooled analysis of these six trials failed to show overall noninferiority; however, the results were strongly affected by the selected treatment (ie, oxaliplatin combined with capecitabine vs oxaliplatin combined with infusional fluorouracil and leucovorin) and risk group (ie, lower risk: patients with smaller tumors [T1–T3] with limited lymph node involvement [N1] vs higher risk: larger tumors [T4] or extensive lymph node involvement [N2]).[22]

In terms of treatment, 3 months of oxaliplatin combined with capecitabine was as effective as 6 months, particularly in the lower-risk subgroup. In patients treated with oxaliplatin combined with infusional fluorouracil and leucovorin, 6 months of therapy resulted in a higher rate of DFS, particularly in the high-risk subgroup.[22]

B.R. has extensive lymph node involvement, and this means he has stage IIIC (ie, higher risk) disease (refer to key website of American Cancer Society guidance for screening, diagnosis, and staging of colorectal cancer), which places him at a high risk of recurrence; therefore, he should receive adjuvant chemotherapy with oxaliplatin and either capecitabine or infusional fluorouracil and leucovorin after surgery. The initial cycle of B.R.'s adjuvant chemotherapy should begin approximately 4 to 6 weeks after his surgery. If oxaliplatin with infusional fluorouracil and leucovorin is used, a total of 6 months of adjuvant therapy should be given. If oxaliplatin plus capecitabine is used, 3 months may be sufficient, but given the high-risk nature of B.R.'s disease, consideration of 6 months of therapy is also warranted.

ADVERSE EFFECTS OF FLUOROURACIL AND OXALIPLATIN

Case 99-2, Question 3: B.R. is scheduled to receive a modified FOLFOX6 (mFOLFOX6) regimen in the adjuvant setting. What potential adverse effects should B.R. be made aware of before receiving this regimen? Are any dose-limiting side effects associated with this therapy? Are there any preventive measures that can be taken to limit the severity of these adverse effects?

The goal of therapy in this setting is a cure; therefore, clinicians typically try to remain aggressive and limit chemotherapy dose reductions or delays while trying to maintain an acceptable toxicity profile. There are a number of chemotherapy-related toxicities that may occur during adjuvant therapy or after its completion.

Toxicities related to fluoropyrimidines include hand-foot syndrome (HFS, also called palmar-plantar erythrodysesthesia), mucositis, diarrhea, hematologic toxicities (neutropenia), photosensitivity, and rarely, cardiac toxicity (vasospastic angina). HFS because of either fluorouracil or capecitabine is managed primarily with supportive-care measures, such as the application of topical moisturizers in addition to temporary withdrawal of fluorouracil-based therapy to allow time to heal (for further discussion of HFS, see Chapter 94, Adverse Effects of Chemotherapy, Immunotherapy, and Targeted Agents). Once healed or decreased in its severity, fluorouracil-based therapy is often resumed at a reduced dose. The frequency and severity of HFS is increased with capecitabine versus fluorouracil.[23] Severe neutropenia is typically managed with chemotherapy dose reductions or delays, and in some cases, clinicians may use the administration of granulocyte colony–stimulating factors, such as filgrastim or pegfilgrastim, to prevent febrile neutropenia while maintaining dose intensity. The incidence of neutropenia is higher with bolus fluorouracil than with infusional fluorouracil or with capecitabine.[24,25] Severe mucositis is uncommon and is mainly associated with bolus fluorouracil.[21,23] Moderate-to-mild symptoms can also occur, however, with capecitabine or infusional fluorouracil, and these can be managed with supportive-care measures, such as mild narcotic pain medications or mouthwashes that contain a local anesthetic such as lidocaine. Strategies for preventing this complication are also important and include stressing the importance of good oral hygiene and avoidance of harsh substances, which may irritate the oral mucosa or inhibit saliva production, such as alcohol, alcohol-based mouthwashes or rinses, spicy foods, and anticholinergic medications. As is the case with many fluorinated pharmaceutical agents, fluorouracil and capecitabine cause photosensitivity, which may result in mild-to-severe sunburns after

sun exposure. Therefore, during fluoropyrimidine therapy, prolonged exposure to direct sunlight should be avoided, and use of a sun block of SPF-15 or higher during outdoor activities is recommended.

Oxaliplatin is the newest member of the platinum family of antineoplastics, and it offers a different antitumor profile and resistance pattern than cisplatin or carboplatin. Of the three agents, oxaliplatin is highly active against colorectal tumors. Myelosuppression, primarily neutropenia and thrombocytopenia, and neurotoxicity are dose-limiting toxicities associated with its use. Oxaliplatin causes an acute, reversible neuropathy consisting of either paresthesias or dysesthesias, and in some instances muscle spasms. The acute phenomenon is reported to occur in >90% of patients receiving oxaliplatin.[26,27] One manifestation of this phenomenon that is particularly distressing for patients is an involuntary laryngopharyngeal dysesthesia that can create the sensation of an inability to swallow or breathe. Although our understanding of the event is limited, it is known to be triggered by direct contact with anything cold. This sensitivity to cold as well as the aforementioned reactions generally occur within minutes of receiving the infusion and can persist up to 7 days. Avoidance of cold objects, including the eating or drinking of cold foods and beverages, should be emphasized to patients after each dose of oxaliplatin. The use of gloves, socks, and scarves can also be recommended, especially in cold weather. Delayed, cumulative neurotoxicity may also occur, and it is potentially irreversible and occurs in a dose-dependent manner. It initially develops in the distal extremities and slowly progresses in a glove and stocking distribution pattern. It is typically characterized by a persistent sensation of numbness, tingling, or burning in the extremities.

Hypersensitivity reactions have also been observed with oxaliplatin use with a reported incidence of 10% to 25%, and although the appearance of the reaction is arbitrary, in that it can manifest with any dose, the median number of doses reported in those that have reacted is seven to nine.[28] Typically, the symptoms of hypersensitivity occur during the infusion, but delayed reactions are also possible. The severity of these allergic reactions can range

from mild itching or flushing to anaphylaxis. After a reaction, mild cases are often managed through premedication with antihistamines or corticosteroids (eg, diphenhydramine 50 mg IV or orally and either dexamethasone 20 mg or another corticosteroid 15 minutes before oxaliplatin IV) in addition to prolonging the infusion of oxaliplatin. More severe reactions generally warrant discontinuation of the drug; however, there are reports in which desensitization protocols have been used successfully, allowing for continued administration.[29,30] Regardless of what is chosen, this strategy accompanies all subsequent doses of oxaliplatin.

Liver toxicity has also been reported with oxaliplatin and is mainly characterized by sinusoidal injury. This can occur in as high as 51% of patients, although blatant liver failure with oxaliplatin is rare. Splenomegaly has been reported to correlate with sinusoidal liver injury, and this manifestation may also contribute to thrombocytopenia that may last long after oxaliplatin is discontinued.[31]

Because B.R. will receive a combination of fluorouracil and oxaliplatin in the adjuvant setting, the toxicities of these agents should be discussed before initiation of therapy. The toxicity of fluorouracil will vary depending on its dose, route, and schedule of administration. At doses used in the treatment of CRC, bolus administration is associated with more severe neutropenia and mucositis, whereas continuous infusion administration is associated with more severe HFS. Fluorouracil is also associated with photosensitivity, so B.R. should be counseled on the use of SPF-15 or greater sunscreen when outdoors because of the increased risk of sunburn. The main toxicities of oxaliplatin are thrombocytopenia, neuropathy, liver toxicity, and hypersensitivity reactions. To minimize the acute neuropathy after each dose, B.R. should be counseled on the avoidance of cold objects, including the eating or drinking of cold foods and beverages. The use of gloves, socks, and scarves can also be recommended, especially in cold weather. B.R. will also have labs drawn at regular intervals prior to administration of chemotherapy to ensure that his neutrophils and platelets are at a

sufficient level to give chemotherapy and to monitor for changes in liver function that can occur with oxaliplatin.

PERIPHERAL SENSORY NEUROPATHY

Case 99-2, Question 4: After eight treatments of adjuvant therapy, B.R. reports a constant numbness and tingling in his toes bilaterally. It is not interfering with his daily activities but is described as more of a nuisance. Which drug is most likely responsible for this, and what course of action should be taken?

As explained earlier, the severity of peripheral sensory neuropathy (PSN) can worsen with continued doses of oxaliplatin and is not readily reversible; therefore, it is imperative that clinicians and patients work together to minimize its negative impact on various activities of daily living such as being able to button a shirt, walking upstairs or downstairs, or realizing whether one's foot is actually touching the brake pedal as the car approaches a red light. In the hallmark clinical trial in the adjuvant setting, during the 6 months of therapy with oxaliplatin, fluorouracil, and leucovorin, 12.5% of patients reported grade 3 PSN; however, this increased to 24.1% in the 18 months after treatment assessment, indicating that PSN will continue to worsen even after cessation of oxaliplatin.[19] It does appear that over time, PSN can improve off oxaliplatin, as at 4 years postadjuvant treatment grade 1, 2, and 3 PSN was observed in 11.9%, 2.8%, and 0.7%, respectively.[26] In the metastatic setting, a "stop-and-go" approach to limit exposure to oxaliplatin while retaining its antitumor effects has been shown to be beneficial in delaying the development of PSN without adversely affecting the outcomes of progression-free survival (PFS) and OS.[32,33] In this approach, oxaliplatin is withdrawn from therapy in patients with metastatic disease and is reinitiated when disease progression is noted. However, in the adjuvant setting where the goal is cure, the benefits of stopping therapy to decrease the risk of permanent PSN must be weighed against the risk of recurrent disease. Newer trials in the adjuvant setting recommend holding oxaliplatin for a period of 4

weeks in the setting of persistent grade >2 neuropathy (defined as persisting between treatments) and resuming at a dose reduction once PSN resolves to grade 1 or less.[25] Further, permanent discontinuation of oxaliplatin is recommended for grade >2 neuropathy that does not resolve within 4 weeks.[25]

Several small trials have been conducted to evaluate the effectiveness of certain pharmaceutical agents in the management of chemotherapy-induced peripheral neuropathy. These trials have focused on either the prevention or treatment of chemotherapy-induced peripheral neuropathy and as a whole have yielded disappointing results. To date, no agent is recommended as a chemoprotectant for the prevention of oxaliplatin-induced PSN. Duloxetine, an antidepressant, has been studied in a randomized clinical trial and has shown to decrease specifically the pain component experienced by some patients with PSN, including oxaliplatin-induced PSN.[34] In addition, tricyclic antidepressants such as nortriptyline and amitriptyline or an anticonvulsant such as gabapentin and pregabalin could be considered as these agents have proven beneficial and are recommended as initial therapy in other neuropathic pain settings.[35,36] It is important to note that when using adjunctive agents such as these to manage neuropathic pain, doses typically require upward titration after initiation. This strategy enables the clinician to find the dose that provides the greatest benefit. It is important to explain to the patient that these agents may take several weeks before a response is seen and that the indication is for the *pain* associated with PSN—these agents have not been shown to improve numbness or tingling. Symptom relief generally requires continued daily use of these agents on a scheduled basis; however, it is important to consider weaning them with time if neuropathic symptoms either improve or show no improvement despite optimal dosing.

The timing of the symptoms that B.R. is experiencing is indicative of the cumulative toxicity oxaliplatin exerts on peripheral sensory nerves. Because B.R. has completed 8 of a planned 12 cycles of his adjuvant therapy and because his symptoms just started, the reaction would be graded as relatively mild in its severity at this

point. He will likely benefit most from continued administration of oxaliplatin at a reduced dosage with diligent monitoring of his neuropathy.

Microsatellite Instability and BRAF

The ultimate goal of treatment is to individualize therapy based on patient and tumor characteristics. Prognostic markers provide information on disease outcome regardless of the treatment provided. Predictive markers provide information on disease outcome based on the treatment provided. As stated previously, in stage II disease, adjuvant therapy is only offered in those patients with high-risk disease. The definition of "high-risk" stage II disease varies among different national guidelines but, in general, includes T4 tumors, <12 lymph nodes examined at surgery, poorly differentiated histology, perforation, and obstruction.[37] There has been increased interest in looking at microsatellite instability and mutations in *BRAF* to determine what patients with stage II disease would benefit from adjuvant therapy.

Microsatellites are short repeating nucleotide sequences that are under surveillance by the mismatch repair (MMR) system. The MMR system is responsible for repair of errors that occur during DNA synthesis. Tumors are found to have microsatellite instability (MSI) if they have a defect in their MMR system. This defect results in the accumulation of mutations of microsatellites. In a pooled analysis of five trials in patients with stage II and III disease where no adjuvant therapy was given, patients with MSI had a longer DFS than those that were microsatellite stable.[32] In addition, in patients with stage II disease that were MSI, those treated with fluorouracil actually did worse in terms of DFS than those that were only treated with surgery.[38] At this time, it appears that MSI is prognostic in that it appears to convey a DFS benefit in stage II disease. It further appears that fluorouracil/leucovorin alone does not convey any benefit in stage II MSI disease. The benefit of adding oxaliplatin to a

patient with high-risk stage II MSI disease is unknown and currently cannot be recommended based on MSI status alone.

The *BRAF* oncogene is downstream from the EGFR receptor. Mutations in *BRAF* have been associated with a poor prognosis, but to date, they lack any predictive value in both early-stage and in advanced disease.[39,40]

Clinical Surveillance for Recurrence

Case 99-2, Question 5: After completing his treatment, how often and for how long should B.R. be monitored for recurrence of his disease?

Because the majority of recurrences occur within the first 2 to 3 years after completion of adjuvant therapy, consensus guidelines have been published that address the importance of patient follow-up and surveillance after definitive therapy for localized disease.[19,41] Both organizations agree that patients treated definitively for localized disease should be monitored regularly for at least 5 years. Because most recurrences occur relatively soon, surveillance screening should be more frequent for the first 2 years and include a history and physical examination, and CEA level performed every 3 to 6 months for these first 2 years, then semiannually thereafter for up to 5 years. In addition, future recommended imaging includes CT scan of the chest, abdomen, and pelvis performed at least annually for up to 5 years and colonoscopy within a year of surgical resection (or ~1 year from the original colonoscopy) and then repeated again in 3 years if no high-grade adenomas are identified. During the surveillance period, development of a concerning symptom on physical examination, an abnormality on a CT scan, or a rise in CEA level above the upper limit of normal (3 ng/mL for nonsmokers or 6 ng/mL for smokers) would necessitate further evaluation for disease recurrence. After the 5-year surveillance period, an increased risk for recurrent disease remains; therefore, screening for CRC every 5 years in these patients will continue rather than the every 10-year screening recommended for the average-risk population.

B.R. should be monitored regularly for at least 5 years. Should B.R. remain disease-free throughout this 5-year surveillance period, he will be considered cured of his cancer. Because most recurrences occur relatively soon, his surveillance visits will be more frequent for the first 2 years with a history and physical examination and CEA level performed every 3 to 6 months, then semiannually thereafter. He should also have a CT scan of his chest, abdomen, and pelvis performed at least annually for 3 years. Another colonoscopy should be performed within a year of his surgical resection or ~1 year from his original colonoscopy, and then repeated again in 3 years.

Chemotherapy for Metastatic Colorectal Cancer

CASE 99-3

Question 1: K.T. is a 64-year-old male treated ~2 years ago with adjuvant chemotherapy for ascending (right-sided) colon cancer, which he tolerated well outside of peripheral neuropathy and which is lingering still. On a routine surveillance visit, his CT scan shows two discrete liver nodules and a nodule in the left lung that are consistent with metastatic disease. The biopsy of the liver was positive for adenocarcinoma of the colon. K.T. is feeling well and has been asymptomatic. Cytogenetics on the tumor was performed, which revealed wild-type *RAS* and *BRAF* status (no mutations), proficiency in mismatch repair proteins, and no amplification in HER2 expression. K.T.'s CBC and chemistry values were as follows:

WBC count, 7.8 × 10^3 cells/μL
Hemoglobin, 13.2 g/dL
Platelet count, 252 × 10^3 cells/μL
Serum creatinine, 1.1 mg/dL
Blood urea nitrogen, 15 mg/dL
Aspartate aminotransferase, 28 units/L
Alanine aminotransferase, 35 units/L
Alkaline phosphatase, 135 units/L
Total bilirubin, 0.8 mg/dL
K.T.'s CEA concentration was 22 ng/mL.

What is the role of chemotherapy now that K.T. has a metastatic recurrence?

Metastatic CRC affects a substantial number of patients. Approximately 20% of patients have metastatic disease at initial presentation, and ≥50% of patients diagnosed at any stage will eventually develop metastatic disease.[2,42]

Significant treatment advances have been made over the last decade for cases of advanced CRC such that the median OS is currently over 2 years in treated patients.[43-45] Treatments tend to include combination therapy (a fluoropyrimidine plus either irinotecan or oxaliplatin) for good performance status (PS) patients and mono-cytotoxic therapy (fluorouracil or capecitabine or irinotecan) for poor PS patients.[19] Alternatively, subsets of patients may be candidates for noncytotoxic treatments (immunotherapy or targeted therapy) when they are not appropriate candidates for intensive therapy.[46-48] Further, agents directed against the vascular endothelial growth factor (VEGF) (eg, the monoclonal antibodies, bevacizumab and ramucirumab, and the soluble decoy receptor, ziv-aflibercept) or against the epidermal growth factor receptor (EGFR) (cetuximab and panitumumab, both monoclonal antibodies) can be added to the chemotherapy backbone in qualifying patients. Given the number of agents currently available and that we tend to talk in terms of regimens (ie, combining agents together) in the treatment of metastatic CRC, it is imperative to consider which agents have greater synergy and less toxicity when combined and how best to sequence these agents, because patients will most likely remain on some type of therapy throughout their disease course.

Irinotecan has been studied combined with a bolus regimen of fluorouracil and leucovorin (IFL) and an infusional regimen (FOLFIRI) as well as with capecitabine (XELIRI or CAPIRI). In general, both IFL and CAPIRI/XELIRI have fallen out of favor because of exorbitant toxicities and less efficacy than FOLFIRI.[19]

Oxaliplatin, as in the early stages of colon cancer, has been studied with both infusional fluorouracil and leucovorin (FOLFOX) or with capecitabine (XELOX or CAPOX) in the metastatic setting. Both strategies of combining oxaliplatin with a fluoropyrimidine in the metastatic setting are equally efficacious, with again, the main

differences being the toxicity profile of capecitabine versus fluorouracil/leucovorin.[49]

In 2007, a phase 3 study did show that combining both irinotecan and oxaliplatin with fluorouracil and leucovorin to give a cytotoxic triplet regimen (FOLFOXIRI) improved response rates (RRs), PFS, and OS when compared to FOLFIRI; however, this was at the expense of increased toxicity (namely grade 2 peripheral neuropathy and grades 3/4 neutropenia) making it less desirable with the majority of patients in the palliative setting.[50]

The decision to start with an oxaliplatin-based regimen (FOLFOX or XELOX) or an irinotecan-based regimen (FOLFIRI) tends to reflect differences in clinical practice rather than clinical outcomes because sequencing studies and the results of multiple individual studies seem to indicate that both regimens are equally efficacious in the first line.[19,32,51] With the optimal sequencing of these regimens remaining unclear, the decision regarding the choice of combination therapy for first- or second-line therapy is based on prior therapy, quality of life, preexisting toxicities, comorbid conditions, and clinical practice where the patient is first seen. Surgery is typically not an option in extensive metastatic disease.

In the past decade, biologic therapies targeting VEGF (bevacizumab, ziv-aflibercept, and ramucirumab) and EGFR (cetuximab and panitumumab) have been incorporated into the treatment of many cases of metastatic CRC. In addition, regorafenib, a multitargeted, orally administered tyrosine kinase inhibitor (TKI) and trifluridine/tipiracil, an orally administered cytotoxic agent, have both been shown to modestly improve OS over placebo as monotherapy in the salvage setting.

TARGETING VASCULAR ENDOTHELIAL GROWTH FACTOR

Bevacizumab is a humanized monoclonal antibody that binds to the ligand of the VEGF-2 receptor, VEGF-A. The addition to bevacizumab in the first line to oxaliplatin-based regimens FOLFOX or XELOX or irinotecan-based FOLFIRI has been shown to increase PFS versus chemotherapy alone, and OS was also improved,

although this seems more pronounced with FOLFIRI than with oxaliplatin-based regimens.[19,34] Bevacizumab has also been added to the cytotoxic triplet FOLFOXIRI and has shown increased RR and PFS compared to FOLFIRI and bevacizumab though not significantly improving OS.[52] A meta-analysis of two phase 3 and three phase 2 trials confirmed RR and PFS benefit of the triplet plus bevacizumab over doublet plus bevacizumab as well as an OS benefit. Again, this was at the expense of increased toxicities (neutropenia, febrile neutropenia, nausea, mucositis, and diarrhea).[53] Bevacizumab, when continued beyond progression in the second-line setting, with either FOLFOX or FOLFIRI, has shown a modest survival benefit of the addition of 1.4 months versus placebo.[54]

Two newer anti-VEGF agents, ziv-aflibercept and ramucirumab, have also been shown to provide a survival benefit to the chemotherapy backbones with which they were studied. However, the differences in how they were studied is important to note in order to apply them in clinical practice. Ramucirumab, a fully human monoclonal antibody that binds to the extracellular domain of the VEGF-2 receptor, has been shown to increase survival versus placebo by 1.6 months when combined with FOLFIRI in patients that progressed on bevacizumab plus FOLFOX.[55] Ziv-aflibercept, a soluble decoy receptor that targets the ligands VEGF-A, VEGF-B, and placental growth factor (PIGF), has also been shown to increase survival versus placebo when combined with FOLFIRI in the second-line setting after progression on oxaliplatin-based therapy; however, in the patients that had previously received bevacizumab, this benefit was less pronounced (around 0.8 months).[56]

TARGETING THE EPIDERMAL GROWTH FACTOR RECEPTOR

The EGFR receptor is overexpressed in the majority of CRCs, making it an attractive target for therapy. However, 56% to 63% of these tumors will possess a downstream mutation in the *RAS* oncogene, a predictive biomarker for a lack of response to EGFR-targeted therapy.[33,41,43] Therefore, prior to consideration of anti-EGFR therapy in any patient with metastatic colorectal disease,

analysis must be undertaken to determine *RAS* status, with anti-EGFR therapy only being offered to those that are *RAS* wild-type.

Cetuximab is a chimeric monoclonal antibody against the extracellular domain of EGFR. It has been studied in the first line with both FOLFIRI and with oxaliplatin-based therapy and is currently approved in combination with FOLFIRI only in the first line for patients that are *RAS* wild-type.[33,57] It is also active as a single agent or in combination with irinotecan even in patients with irinotecan-refractory malignancies.[58] Panitumumab, a fully human monoclonal antibody also targeting the extracellular domain of EGFR, has been shown in patients that are *RAS* wild-type to improve OS in the first-line setting when combined with FOLFOX and in the second-line setting combined with FOLFIRI in patients that had progressed on an oxaliplatin and bevacizumab-containing regimen.[59,60] It may also be used as monotherapy in patients that have progressed on oxaliplatin- and irinotecan-based therapy. Both panitumumab and cetuximab have been paired with FOLFOXIRI in phase 2 trials. Despite increases in RR, there has not been a proven PFS or survival advantage and currently is not a recommended practice.[61,62] The trials of combining cetuximab or panitumumab with bevacizumab and chemotherapy have resulted in a decrease in PFS and increased toxicity, so this combination should not be used.[63,64] The choice of whether cetuximab or panitumumab is chosen as the anti-EGFR agent is more a matter of local practice and differences in prescribing habits than being data-driven. They have been compared to each other in the salvage setting as monotherapy and are considered equally efficacious, with the main difference being a slightly higher rate of infusion reactions with cetuximab versus panitumumab (13% vs 3%).[65] In addition, there is currently no data to support the use of one of these agents after proven progression on the other agent.

TARGETING VASCULAR ENDOTHELIAL GROWTH FACTOR VERSUS EPIDERMAL GROWTH FACTOR RECEPTOR IN FIRST-LINE TREATMENT

Two randomized, phase 3 trials have compared chemotherapy plus anti-VEGF therapy (bevacizumab) against chemotherapy plus anti-EGFR therapy (cetuximab) in the front-line treatment of patients with metastatic CRC whose tumors were *KRAS* wild-type (incomplete *RAS* testing though the standard of care at the time of the study).[45,66] The results of these two trials were difficult to draw conclusions from; neither showed a difference in PFS, but OS results were discordant. One trial favored anti-EGFR therapy, whereas the other failed to show an OS difference between anti-EGFR therapy versus anti-VEGF therapy, both paired with chemotherapy. A *post hoc* analysis of these two trials evaluated a patient population that are fully *RAS* wild-type and also considered "sidedness" of the initial tumor (ie, whether the primary tumor arose from the right- or left side of the colon).[67,68] Both of these *post hoc* analyses revealed OS benefits with first-line anti-EGFR in left-sided *RAS* wild-type tumors; however, the results were mixed for PFS. Further, anti-EGFR therapy did not confer any benefit to patients that are *RAS* wild-type with right-sided tumors. The results of these analyses led to consensus guidelines recommendations that patients with right-sided colon cancers should not be offered anti-EGFR therapy in the front-line setting regardless of *RAS* mutation status. It is to be noted that at the present time, there is no data showing detriment for anti-EGFR therapy in *RAS* wild-type right-sided tumors beyond the front-line treatment setting. Despite disparate mechanisms of action and toxicity profiles between anti-VEGF and anti-EGFR agents, the trials of combining cetuximab or panitumumab with bevacizumab and chemotherapy have resulted in a decrease in PFS and increased toxicity, so this combination should not be used.[63,64]

K.T. has stage IV colon cancer with metastasis to the liver and lung. The goal of therapy for K.T. is prolongation of survival as well as prevention and palliation of any cancer-related symptoms. At this point, K.T.'s cancer is not curable. K.T. still has a good PS and should receive combination chemotherapy. Standard first-line chemotherapy involves fluoropyrimidine in combination with oxaliplatin or irinotecan. Given lingering peripheral neuropathy from his prior adjuvant therapy, oxaliplatin is less appealing, so FOLFOX

and FOLFOXIRI are less appropriate. Because K.T.'s tumor originated in the ascending colon (right side), adding anti-EGFR monoclonal antibody at this point is not considered a first-line treatment option. Addition of bevacizumab to this regimen will further improve RR and survival of K.T. In this case, K.T. is scheduled to receive the FOLFIRI plus bevacizumab regimen, which is given every 2 weeks. He will receive this chemotherapy regimen until disease progression. The FOLFIRI plus bevacizumab is given as bevacizumab 5 mg/kg IV for 10 to 30 minutes, leucovorin 200 mg/m^2 IV for 2 hours, irinotecan 180 mg/m^2 IV for 90 minutes, and fluorouracil 400 mg/m^2 given as a bolus, which is then followed by 2400 mg/m^2 infused for 46 hours.

IMMUNOTHERAPY FOR MICROSATELLITE INSTABILITY HIGH TUMORS AND TUMOR MUTATION BURDEN-HIGH CANCER

Immunotherapies have broadly made their way into different areas of oncology; initially, patients with CRC did not seem to benefit from these agents, but recently there have been advances in specific subsets of patients.[69-71] Patients who have microsatellite instability high (MSI-H) tumors, as evidenced directly by elevated numbers of microsatellites through polymerase chain reaction (PCR) testing or indirectly by deficiencies in mismatched repair (dMMR) proteins, have RRs to immune checkpoint inhibitors in the range of 30% to 55%, including complete responses in up to 20% of patients.[72-75] Two programmed death receptor-1 (PD-1) blocking antibodies, pembrolizumab and nivolumab are approved for the treatment of patients with metastatic CRC whose tumors are deficient in MMR and has progressed following treatment with a fluoropyrimidine, oxaliplatin, and irinotecan, given as single agents. The combination of nivolumab and ipilimumab, a human cytotoxic T-lymphocyte antigen 4 (CTLA-4)–blocking antibody, has also been approved in this treatment setting. Although single-agent immunotherapy has not been compared to the combination regimen, the RRs appear to be higher with nivolumab plus ipilimumab, but the data has not matured regarding survival benefits and must also be weighed against the

potential for increased autoimmune adverse effects.[75] Pembrolizumab is also approved as a first-line treatment option in patients with dMMR metastatic CRC as it has doubled PFS when compared to traditional chemotherapy.[76,77] However, although promising, patients with mismatch repair deficient CRC represent only a small subset of patients with metastatic disease (~3% of the population vs ~22% of those with stage II colon cancer and ~12% of those with stage III colon cancer).[69] Approval for pembrolizumab and nivolumab with or without ipilimumab was based on tumor RR and durability of response and as a condition of accelerated approval, further studies are required to confirm the clinical benefit of these agents for this indication.

On June 16, 2020, pembrolizumab received an accelerated approval for patients with a high tumor mutation burden (TMB-H) as defined by ≥10 mutations per megabase (mut/Mb).[71] This approval is not colon cancer-specific but for any solid tumor that reached this TMB threshold and has exhausted satisfactory treatment alternatives.[46] Although this is not prevalent, it adds to the potential use of immunotherapy in metastatic CRC treatment. This indication was also approved under accelerated approval based on tumor RR and duration of response and requires confirmatory trials to sustain this approval.

TARGETING BRAF V600E MUTATIONS

BRAF V600E, a serine/threonine-protein kinase oncogene that resides directly downstream of the *RAS* oncogene has been found to be mutated in 5% to 9% of metastatic CRCs and is all but mutually exclusive of RAS mutations (concomitant rate ~0.001%).[40,78,79] *BRAF* V600E mutations are more common in right-sided colon cancers and tend to carry a poor prognosis with limited response to traditional chemotherapy treatments. *BRAF* inhibition alone has failed to produce clinical benefit in CRC because of feedback upregulation of EGFR expression.[80] Dual inhibition of *BRAF* and EGFR has improved RRs and OS when compared against standard of care chemotherapy in the second-line or higher treatment setting.[81] This

chemotherapy-free regimen of encorafenib, a kinase inhibitor of *BRAF*, and cetuximab is Food and Drug Administration (FDA) approved for patients with metastatic CRC that harbor a *BRAF* V600E mutation and have received prior treatment. All patients with metastatic CRC should be tested for *BRAF* V600E mutations.

TARGETING HUMAN EPIDERMAL GROWTH FACTOR RECEPTOR 2 AMPLIFICATIONS

Human epidermal growth factor receptor 2 (HER2) amplifications have been well studied in breast and gastric cancers where its prevalence approximates 20% of these patients.[82,83] Metastatic CRCs can also overexpress HER2, although in only 3% of patients.[47,48] Because of its rarity in CRC, treatments targeting HER2 amplifications are still in their infancy. Two small studies have shown RRs using dual HER2 blockade in the salvage setting at 30% to 32%, whereas approved therapies in this setting have had dismal RRs of ~1.5%.[47,48,84,85] Both studies incorporated trastuzumab, an anti-HER2 monoclonal antibody; one study coupled the oral intracellular TKI of HER2, lapatinib, with trastuzumab and the other trial used pertuzumab, another anti-HER2 monoclonal antibody with an alternate binding site, in combination with trastuzumab. Although the numbers of patients with both HER2 amplifications and *RAS* mutations treated in these studies are small (one study excluded these patients), there appears to be lower RRs to HER2-directed therapy in this population.[48] Despite the lack of FDA approvals for HER2-directed therapies in patients with metastatic CRC with HER2-amplifications, national expert consensus guidelines recommend the use of either HER2-targeting doublet regimen in subsequent lines of therapy as long as the patient does not have a *RAS* or *BRAF* mutation. All patients with metastatic CRC should be tested for HER2-amplifications unless a *RAS* or *BRAF* mutation has already been identified.

Pharmacogenomics of Irinotecan and Fluorouracil

Case 99-3, Question 2: Fourteen days after receiving FOLFIRI plus bevacizumab, K.T. presented to the emergency room with a fever (101.2 °F [38.44 °C]). On further evaluation, K.T. was identified as having febrile neutropenia with a WBC count of 1.2×10^3 cells/μL and an absolute neutrophil count of 650 cells/μL. He was admitted to the hospital for treatment. Is there an accurate method for predicting this outcome in K.T.? Can K.T. continue to receive this therapy?

Recent discoveries in the field of pharmacogenomics have identified several important genetic variations (polymorphisms) that partly account for interpatient variability regarding the tolerability and efficacy of some drug therapies. Dihydropyrimidine dehydrogenase (DPD) is the rate-limiting enzyme responsible for the breakdown of fluorouracil to dihydrouracil and eventually to fluorinated β-alanine. The cytotoxic effects of both fluorouracil and capecitabine can only occur after conversion to active metabolites, and the amount of fluorouracil available for this conversion is determined by the extent of its breakdown.[86] DPD is subject to genetic polymorphism, which can lead to a deficiency in its activity.[87] Approximately 3% to 5% of the population will have a partial DPD deficiency, with 0.2% of the population estimated to have complete loss.[88,89] Although several tests are currently available that attempt to identify this deficiency, no single test has the specificity and positive/negative predictive values to accurately predict a true lack of enzyme activity.[90] Further, most studies to date that evaluated testing for DPD deficiency prior to administration of fluorouracil-based therapy only addressed reduced toxicity with dose reduction at initiation of therapy for those patients that were DPD-deficient, but not whether dose reduction was actually necessary.[91-93]

Extreme and potentially life-threatening adverse effects from fluoropyrimidines may be because of genetic polymorphisms such as DPD deficiency, medication overdose (incidental or intentional), as well as many less understood or identifiable causes.[94] These can

manifest as central nervous system toxicity, cardiotoxicity or severe cases of mucositis, diarrhea, or myelosuppression, namely neutropenia.[95] For patients experiencing any of these symptoms deemed severe or life-threatening within 96 hours following fluorouracil or capecitabine administration or with a known or suspected overdose of these agents regardless of symptoms, uridine triacetate was approved for emergency use. Uridine triacetate is an oral prodrug of uridine, which competitively inhibits cell damage and cell death caused by fluorouracil.[94] Based on two open-labeled studies using uridine triacetate to emergently treat fluoropyrimidine overdose or early-onset severe symptoms, a 30-day survival rate of 94% was observed, and this was compared to a historical case-cohort rate of 14% based on literature review database reporting and medical safety agency data.[96] Uridine triacetate is given orally every 6 hours for a total of 20 doses and should be initiated within 96 hours of completing fluoropyrimidine treatment when indicated. The cost of a 20-dose course of uridine triacetate is ~$75,000, so critical selection of appropriate patients is warranted.

Uridine diphosphate glucuronosyltransferase (UGT) enzymes are responsible for the glucuronidation of bilirubin and other endogenous substrates as well as drugs and other toxins.[97] The enzyme UGT1A1 is responsible for the glucuronidation of SN-38, the active metabolite of irinotecan. Reductions in glucuronidation and accumulation of SN-38 are associated with greater toxicity. Of the known genetic polymorphisms of UGT1A1, one polymorphism in particular (UGT1A1*28) has been associated with decreased glucuronidation and therefore prolonged exposure to SN-38.[98,99] Studies have shown that those homozygous for the UGT1A1*28 allele are at an increased risk of neutropenia.[98] Although not consistently observed among trials, severe diarrhea has also been observed with genetic polymorphisms of UGT1A1.[98] However, although the ability to test for this polymorphism is available, the low sensitivity (ie, the ability of this test to correctly identify all patients at risk of severe neutropenia) and the lack of consensus guidelines that outline how to use the results limit its widespread use in clinical practice.[98] However, practitioners should still exercise caution when treating patients with

either a known or suspected deficiency in dihydropyrimidine dehydrogenase or a known polymorphism in UGT1A1.

K.T. should receive empiric antibiotic therapy, and his chemotherapy should be held until both his fever and neutropenia resolve. Because he did not experience febrile neutropenia with his previous adjuvant therapy, it is unlikely he would harbor a DPD deficiency. A dose reduction of fluorouracil could be considered. More importantly, a reduction of his irinotecan dose is warranted before resuming his chemotherapy to reduce the risk of fever and neutropenia with consecutive cycles. The FDA-approved Invader® UGT1A1 molecular assay is commercially available to detect the UGT1A1*28 polymorphism. If it is known that a patient has this polymorphism, an empiric reduction in the dose of irinotecan is recommended; however, its use is not generally recommended for determining reductions of subsequent doses of irinotecan after a toxic event. Uridine triacetate would not be appropriate in this scenario as K.T.'s symptoms are more likely attributable to irinotecan. In addition, he is outside the 96-hour window from treatment, and there is no reason to believe that he received an overdose of fluorouracil, and although his adverse effects are concerning, they can be managed with alternate supportive-care measures.

Adverse Effects of Fluorouracil, Irinotecan, and the Vascular Endothelial Growth Factor Inhibitors

Case 99-3, Question 3: K.T. was discharged from the hospital after 4 days without identification of any infection. K.T. presents to clinic to receive a second cycle of FOLFIRI plus bevacizumab. He is now more cognizant of chemotherapy's adverse effects. He states that after his first cycle of chemotherapy, he also experienced abdominal cramping followed by profuse watery bowel movements for 3 days. He reported periods of nose bleeds lasting up to 2 weeks as well, which he never had in the past. The following laboratory values were also noted:

WBC count, 4.5×10^3 cells/μL
Hemoglobin, 12.5 g/dL

Platelet count, 210,000 cells/μL
Serum creatinine, 1.3 mg/dL

Given K.T.'s recent hospitalization for fever with neutropenia, his doses of both irinotecan and fluorouracil have been reduced for this next cycle. Additionally, what supportive care options should be employed to help K.T. with the diarrhea he reported?

The incidence of irinotecan-induced diarrhea varies depending on the dosing schedule used and its combination with other chemotherapeutic agents. Trials in metastatic CRC have reported rates of grade 3 or 4 diarrhea of 20% to 30% depending on which irinotecan-based regimen is used.[30,100] The active metabolite of irinotecan, SN-38, is capable of producing acute abdominal cramping and diarrhea, which is a cholinergic-mediated process. Administration of subcutaneous or IV atropine at doses typically lower than those used in the cardiac setting is recommended for the treatment of acute diarrhea caused by irinotecan. The occurrence of diarrhea can also be delayed; thus, the use of an oral antidiarrheal is recommended if this occurs. A regimen of oral loperamide 4 mg with the first loose bowel movement, followed by 2 mg every 2 hours during the day or 4 mg every 4 hours in the evening, is recommended until the patient is diarrhea-free for a period of 12 hours.[101] If severe diarrhea symptoms persist for more than 48 hours in spite of these measures, patients should be instructed to seek emergency medical attention. Insufficient hydration resulting from diarrhea may lead to electrolyte losses and life-threatening consequences.

The key adverse effects of fluorouracil, oxaliplatin, and irinotecan are discussed under Case 99-2, Questions 3 and 4, and Case 99-3, Question 2. Although the VEGF inhibitors (bevacizumab, ziv-aflibercept, and ramucirumab) may share some overlapping toxicities with traditional chemotherapy, the majority of their effects are unique. Although cytotoxic agents are associated with myelosuppression, antiangiogenesis agents (ie, VEGF inhibitors) do not target proliferating cells. Hence, they do not cause this type of toxicity. All VEGF inhibitors carry the risk of grade 3 or 4 bleeding events and

gastrointestinal perforation which, although severe and require immediate medical attention, are also relatively rare (>3% and >2% with bevacizumab, respectively).[102] Other adverse events deemed as VEGF inhibitor related are arterial thrombosis, hypertension, proteinuria, and wound-healing complications.[103] Monitoring of blood pressure and the pharmacologic management of diagnosed hypertension while on VEGF inhibitor therapy is essential. In addition, because of the wound-healing complications, the use of VEGF inhibitors should be stopped at least 6 to 8 weeks prior to planned surgery and should not be resumed until the patient has fully healed (at least 4–6 weeks).[104,105] Finally, a rare but serious side effect of posterior reversible encephalopathy syndrome (PRES) has been reported with agents that target VEGF including bevacizumab, requiring immediate medical attention and discontinuation of therapy.[106,107]

The epistaxis K.T. is experiencing with this cycle of chemotherapy may be attributed directly or indirectly to his current regimen. Although fluorouracil and irinotecan may also cause bleeding, this is usually related to their myelosuppressive effects on platelet progenitors. Because K.T. has a platelet count of 210,000 cells/μL on his recent laboratory work, this bleeding is more likely associated with bevacizumab use.

Case 99-3, Question 4: About 10 months into his treatment, K.T. had a CT scan that suggested progression of the liver and lung masses. His prior cytogenetic results showed wild-type *RAS* and no mutation of *BRAF*. K.T. still has lingering peripheral neuropathy. What should be the best second-line treatment option for K.T.'s metastatic disease?

K.T. has not received anti-EGFR monoclonal antibody–based chemotherapy. As tumor tissue analysis revealed that it contains wild-type *RAS* and negative *BRAF* cytogenetics, K.T. may receive benefit from anti-EGFR monoclonal antibodies. Remembering that right-sided colon cancers do not benefit from anti-EGFR therapy in the front line is concerning, but there is no data to show that it fails to work in additional lines of therapy and reintroducing an oxaliplatin-

based regimen would be concerning given his residual peripheral neuropathy. Irinotecan in combination with EGFR antibodies has synergistic activity; therefore, a regimen of irinotecan and anti-EGFR (cetuximab or panitumumab) combination would be a good choice. In many cases, the fluoropyrimidine is continued as well.

Adverse Effects of Epidermal Growth Factor Receptor Inhibitors

DERMATOLOGIC REACTIONS

Case 99-3, Question 5: K.T. will receive the following combination chemotherapy regimen: FOLFIRI (dosed as before with the dose reductions for irinotecan as previously noted because of his episode of febrile neutropenia) and cetuximab at 500 mg/m^2. Each cycle is to be repeated every 2 weeks. What is the most common adverse effect K.T. is likely to experience with his new anti-EGFR therapy? How can this toxicity be minimized?

In addition to diarrhea, dermatologic toxicity related to EGFR therapy occurs in more than 90% patients with metastatic CRC treated with these agents. EGFR skin reactions typically occur within 7 to 10 days of therapy and most often present as a maculopapular rash on the face or upper torso of patients.[108] The rash may cause discomfort and reduce the quality of life. Both cetuximab and panitumumab have recommendations for dose reductions or the withholding of therapy based on rash severity. Collaborative efforts have been made across clinical disciplines to develop treatment strategies for EGFR-induced dermatologic toxicities based on their severity. Strategies for preventing or limiting the severity of EGFR dermatologic toxicities have also been explored, including the use of a daily regimen of skin moisturizer, sunscreen, topical 1% hydrocortisone cream, and doxycycline.[109] In addition to their antimicrobial properties, the tetracycline class of antibiotics possesses anti-inflammatory properties and anti-proliferative effects on lymphocytes, which makes it a reasonable class of agents to consider given the proposed mechanisms involved in EGFR rash

development. Two studies have revealed that the use of either minocycline or doxycycline as preemptive treatment (ie, given prior to the first dose of either cetuximab or panitumumab and continued throughout therapy) can significantly reduce the severity of the rash but not the overall incidence of occurrence.[110,111]

K.T. would most likely develop an EGFR inhibitor rash. A strategy focused on skin moisturization and protection combined with a daily application of hydrocortisone cream and the administration of doxycycline 100 mg twice daily or another tetracycline derivative could also be considered.

INFUSION-RELATED REACTIONS

Case 99-3, Question 6: K.T. comes in for his first dose of cetuximab with FOLFIRI. Within minutes of receiving the initial cetuximab infusion, K.T. becomes hypotensive and begins having difficulty breathing. What measures should be taken as quickly as possible?

The incidence of grade 3 or 4 infusion-related reactions reported in clinical trials is <3.5% with cetuximab and even less for panitumumab.[58,59,78,112] Because cetuximab is a chimeric monoclonal antibody, the higher incidence of reactions is not surprising. Therefore, cetuximab administration requires premedication with diphenhydramine, whereas panitumumab does not. Although the incidence estimate for hypersensitivity is <5%, these reactions may be underestimated, especially in the middle southern region of the United States where a higher incidence has been observed.[113] It is not currently known why there is a greater propensity for severe hypersensitivity reactions in patients in this region of the country.

Because of the severe nature of the reaction experienced by K.T., rechallenging with cetuximab at this point would be contraindicated.

Salvage Therapy in Metastatic Colorectal Cancer

Regorafenib, a multi-kinase inhibitor targeting VEGF, as well as multiple other protein kinases (KIT, RET, BRAF, PDGFR, and FGFR), was approved in the United States for use in metastatic colon cancer. It is currently used as salvage therapy (ie, in patients who have been previously treated with fluoropyrimidine-, oxaliplatin-, and irinotecan-based chemotherapy, with an anti-VEGF therapy, and, if *RAS* wild-type, with an anti-EGFR therapy). Regorafenib has been shown versus placebo to provide a modest survival advantage of 1.4 months in this patient population. The FDA-approved dose of regorafenib is 160 mg (four 40-mg tabs) orally once daily for 3 weeks followed by 7 days off of therapy. However, toxicity and its management are very important, with the most common grade 3 or higher adverse events being HFS, fatigue, diarrhea, hypertension, and rash.[84] Because of significant tolerability issues, most patients cannot tolerate the approved dose, and alternate dosing strategies may be used in clinical practice. A common modification was studied in a phase 2 trial that compared full-dose therapy to weekly-dose escalation starting at 80 mg daily and increasing by 40 mg/day each week up to the approved dose of 160 mg as tolerated in the first cycle.[114] The primary end point of keeping patients on therapy longer with the dose escalation strategy was met, grade 3 adverse effects were generally lower, as well as improvements in PFS and OS were seen in the dose escalation arm, although they did not reach statistical significance. Regorafenib has a half-life of 26 to 28 hours with two active metabolites (M2 and M5) with M5 having a half-life of 48 hours, which, owing to its anti-VEGF properties, is important to consider as the same precautions apply for bleeding risk and wound-healing issues as for the traditional VEGF inhibitors.

Trifluridine, a thymidine-based nucleic acid analog, combined with tipiracil hydrochloride, a thymidine phosphorylase inhibitor, is another oral agent approved in the salvage setting for metastatic colon cancer. Trifluridine is the active cytotoxic agent, and tipiracil prevents the rapid degradation of trifluridine once administered.[115,116] It is administered at a dose of 35 mg/m^2 (based on the trifluridine component) orally once daily on days 1 to 5 and days 8 to 12 of each 28-day cycle. Compared with placebo in the salvage setting, it has

also been shown to convey a modest survival benefit of 1.8 months; however, unlike targeted therapy, trifluridine/tipiracil is cytotoxic and as such has more of the traditional chemotherapy side effects.[85] The main grade 3 or higher toxicities associated with trifluridine/tipiracil were hematologic (ie, neutropenia, anemia, and thrombocytopenia).[85]

CHEMOTHERAPY AND RADIATION FOR EARLY-STAGE RECTAL CANCER

Approximately one-third of newly diagnosed CRCs originate from the rectum.[4] The differentiation between cancers of the colon and rectum lies in their location and their propensity for recurrence at or near the site of origin after treatment. If the location of B.R.'s tumor had been within 12 to 15 cm from the anal verge, he would have been diagnosed with rectal cancer (Case 99-2). The main difference between rectal cancer and colon cancer treatment lies primarily in patients with stage II or stage III disease. Unless contraindicated, radiation therapy is incorporated into the treatment plan of patients with stage II or stage III disease of the rectum. In addition, slightly different surgical techniques are used, and a short course of fluorouracil or capecitabine chemotherapy is administered in combination with the radiation until it is complete. When combined with chemotherapy, radiation can significantly reduce local recurrence rates.[117-119] An area of debate is the timing of both chemoradiotherapy and chemotherapy. Both chemoradiotherapy started before (neoadjuvant) or after surgery (adjuvant) appear to be equally effective, so other issues are considered when choosing one modality over the other. Adjuvant chemoradiotherapy may avoid overtreatment of disease, whereas a neoadjuvant approach of chemoradiotherapy before surgery has the advantage of potentially shrinking the tumor and giving the surgeon a greater chance of obtaining negative margins, perhaps allowing for a less radical

procedure and preservation of the anal sphincter. Taken altogether, national consensus guidelines now recommend preoperative chemoradiotherapy for stage II or III rectal cancer and reserve postoperative chemoradiotherapy for rectal cancers with preoperative stage I disease that were found to be stage II or III after surgery. In addition to chemoradiotherapy, patients with stage II and III rectal cancer should receive additional chemotherapy (FOLFOX or CAPEOX for 4 months) for a total of 6 months perioperative treatment (chemoradiotherapy accounts for 2 months of treatment). Traditionally chemotherapy was given after surgery, although there is an evolving practice of combining preoperative chemotherapy with preoperative chemoradiation for a total neoadjuvant therapy approach referred to as the TNT approach.[120] The hypotheses for using a TNT approach are increasing complete RRs, earlier treatment of micrometastatic disease, and improving the tolerability and completion of chemotherapy. As the TNT approach is emerging, there is also uncertainty as to the preferred order of chemotherapy in relation to chemoradiotherapy. Although it appears there are higher complete RRs prior to surgery when chemoradiotherapy is used first, the data have not matured to draw conclusions on survival outcomes.[121] Currently, it is acceptable to treat stage II and stage III rectal cancers with preoperative chemoradiotherapy in combination with chemotherapy that may be given before or after chemoradiotherapy or after surgical resection.

Another difference between tumors of the rectum and colon is the vascular drainage by the venous system. The colon is drained by the mesenteric veins of the hepatic portal system, whereas more distal portions of the rectum are drained by veins that empty into the inferior vena cava. This plays a role in the initial site of metastatic development for each disease. Although the liver is the most common overall site of CRC metastasis, when compared to the colon, cancers of the distal rectum are more likely to metastasize to the lungs because of the differences in their respective vasculature.

Prostate Cancer

Marina D. Kaymakcalan and Christy S. Harris

CORE PRINCIPLES		CHAPTER CASES
1	Risk factors for the development of prostate cancer include age, family history, and ethnicity.	**Case 100-1 (Questions 1, 2), Figures 100-1, 100-2**
2	Screening by means of prostate-specific antigen (PSA) testing with or without a digital rectal exam allows for early identification of prostate cancer. However, it is acknowledged that prostate cancer has been overdiagnosed in many males.	**Case 100-1 (Question 3) Case 100-2 (Question 1), Table 100-1**
3	The PSA, grade group, and tumor stage can determine the aggressiveness of the prostate cancer. They are considered prognostic factors for the risk of recurrence.	**Case 100-2 (Questions 2, 3), Table 100-2, Figure 100-3**

CORE PRINCIPLES		CHAPTER CASES
4	Most prostate cancers are slow growing, and some males may not ever develop symptoms of disease. Therefore, observation and active surveillance are options for certain males with early-stage disease and shorter life expectancies.	**Case 100-2 (Question 4)**
5	Treatment of localized disease includes surgery, radiation, and/or androgen deprivation therapy (ADT). ADT is first-line treatment for advanced prostate cancers. It lowers testosterone in the body to a castrate level of ≤50 ng/mL. This can be accomplished through surgical (orchiectomy) or chemical (gonadotropin-releasing hormone analog) means.	**Case100-2 (Question 5) Case 100-3 (Questions 1, 2), Table 100-3, Figure 100-4**
6	Castration-resistant prostate cancer (CRPC) occurs when the cancer has acquired a mechanism of resistance in the presence of hormonal therapy and is no longer responding to ADT alone.	**Case 100-3 (Question 3)**
7	Cytotoxic chemotherapy, hormonal therapy, immunotherapy, androgen-directed therapy, or targeted therapy may be used in metastatic disease. Metastases often occur in the bone, requiring therapy to decrease skeletal-related events.	**Case 100-4 (Questions 1, 2)**

CORE PRINCIPLES		CHAPTER CASES
8	Complications of prostate cancer include urinary and sexual issues, but may not be a problem until the disease is advanced. Adverse effects of therapy include cardiovascular and metabolic issues.	**Case 100-5 (Question 1) Case 100-2 (Question 5) Case 100-6 (Question 1)**
9	Prevention of prostate cancer with finasteride or dutasteride has been studied, and may be an option for select males with high risk.	**Case 100-7 (Question 1)**

INTRODUCTION

Prostate adenocarcinoma is the most common malignancy in American males and is the second leading cause of cancer death in males in the United States. It is a disease occurring mainly in older males, with the average age of diagnosis being 66 years.[1] The incidence of prostate cancer is estimated to be 248,530 cases with 34,130 deaths in 2021, which correlates to 1 chance in 8 of eventually being diagnosed with prostate cancer and about 1 chance in 41 of eventually dying of it.[2] Progress in treatment and increased public awareness has improved the overall 5-year relative survival to 97.8%.[1] Because of the widespread use of screening, prostate cancer is being found in earlier stages, which allows for the possibility of an earlier treatment that is less invasive with fewer adverse effects. Ninety percent of patients are diagnosed in the local or regional stage of disease and have a 5-year survival of nearly 100%. Patients initially diagnosed with metastatic disease only have a 5-year survival of 31%.[1]

Guidelines that are designed to screen males to detect significant cancers while trying to avoid the harm of overdetection and overtreatment of inconsequential disease are available (**Table 100-1**).

Table 100-1
Prostate Cancer Screening Guidelines for Average and Elevated Risk Patients

	Average Risk	Elevated Risk
American Cancer Society[21]	Informed and shared decision-making beginning at age 50 If PSA <2.5 ng/mL, repeat every 2 years. If PSA ≥2.5 ng/mL, repeat annually. <10-year life expectancy: If asymptomatic, offer no screening.	Higher risk (African American, first-degree relative diagnosed before age 65): informed and shared decision-making beginning at age 45 Appreciably higher risk (multiple first-degree relatives diagnosed before age 65): informed and shared decision-making beginning at age 40 <10-year life expectancy: If asymptomatic, offer no screening.
American Urological Association[22]	Age 55–69: shared decision-making; screening every 2 or more years Age ≥70 or life expectancy <10–15 years: no screening recommended	High risk (African American or family history) Age ≤55: individualized decision
U.S. Preventive Services Task Force[23]	Age 55–69: The decision of whether to undergo screening or not should be individualized. Age ≥70: no screening recommended	

DRE can be considered, particularly in patients with an elevated PSA, as an adjunct to PSA for screening. However, it should never be used as a stand-alone test.

DRE, digital rectal exam; PSA, prostate-specific antigen.

PATHOPHYSIOLOGY

The prostate is a walnut-shaped gland that sits directly below the bladder and is anterior to the rectum, with the urethra running through the center. This location gives rise to many of the urinary, rectal, and sexual symptoms that males may experience in advanced cancer. The prostate consists of lobular glands that produce the fluid that protects and nourishes the sperm cells within the semen. This fluid is also rich in prostate-specific antigen (PSA), a glycoprotein that enhances sperm motility.[3] Cells within the prostate convert testosterone into the more potent dihydrotestosterone (DHT) by the enzyme 5-α-reductase, which stimulates growth of the cells within the prostate. Cancer can often be found confined within the capsule of the prostate if discovered early or may extend out of the capsule into the surrounding seminal vesicles and bladder neck. Eventually, systemic spread can occur via the lymphatics to involve the bone, lung, or liver.[4]

CLINICAL PRESENTATION AND DIAGNOSIS

Because of the ability to screen for prostate cancer for early identification and because some prostate cancers are slow growing, symptoms are rarely present at the time of diagnosis. Symptoms usually manifest after the cancer has spread beyond the prostate. At that point, the most common sign in males age older than 50 years is bladder outlet obstruction, including hesitancy, nocturia, incomplete emptying, and diminished urinary stream. In metastatic disease, bone pain, anemia, or pancytopenia may be present.[4]

The use of routine serum PSA testing in males at risk for prostate cancer allows for early detection and diagnosis of prostate cancer, although rises in the serum PSA do not automatically indicate cancer. Although PSA is highly specific to the prostate, it is not specific to cancer, with an overall sensitivity of ~21% to 68%.[5]

Normal PSA levels in the blood are generally considered to be <4 ng/mL, but begin to rise in males as they age, often in the setting of benign prostatic hypertrophy (BPH). Median PSA levels are 0.7 ng/mL in ages 40 to 49 years and 0.9 ng/mL in ages 50 to 59 years.[6] Factors that can falsely elevate PSA levels are inflammation of the prostate, urinary retention, prostatic infection, ejaculation, or trauma.

Certain medications and supplements can affect PSA levels, which warrant a careful review of a patient's medication history. The 5-α-reductase inhibitors can cause a decrease in the serum PSA also lower PSA levels.[9] by up to 50%.[7,8] Some herbal supplements, such as lycopene and soy, may also lower PSA levels.[9] Males with PSA levels of 4 to 10 ng/mL have a 1 in 4 chance of having prostate cancer. If the level increases >10 ng/mL, there is a >50% risk of a prostate cancer diagnosis.[10] Although the use of serum PSA levels is the optimal tool for screening, PSA alone may not be adequate for screening and diagnosis because up to 15% of men with prostate cancer do not produce PSA elevations that would typically prompt a biopsy.[11] There are several adjunctive clinical, laboratory, and imaging tests that have been developed to further define a patient's risk or likelihood of prostate cancer and to guide the decision for prostate biopsy. A digital rectal exam (DRE) may be performed in conjunction with the PSA level during prostate cancer screening. The placement of the prostate directly in front of the rectum allows the practitioner to feel the outside of the prostate, which should be smooth without any nodules, indurations, or asymmetry felt, which might be suspicious for cancer. Magnetic resonance imaging (MRI) can be used to better select patients who may need a biopsy and can also be used during a biopsy to help target areas of the prostate with clinically significant disease.[12] PSA derivatives and other tests exist as an adjunct to serum PSA testing to potentially improve specificity of prostate cancer detection and decrease unnecessary biopsies.

To definitively diagnose prostate cancer, transrectal ultrasound (TRUS)-guided needle biopsy is the standard approach. It is important to obtain ≥10 core biopsies in a single setting because differences in pathology can be seen within different cores.

Treatment will be decided by the extent and aggressiveness of the disease along with the overall health and life expectancy of the patient. Staging of prostate cancer determines the extent of the disease using the TNM (T, tumor size, N, node status, and M, sites of metastases) classification from the American Joint Committee on Cancer (AJCC), although clinically it is usually referred to as localized, locally advanced, regional, and metastatic disease. Aggressiveness is determined by the grade and rate of growth of the cancer cells[4] (**Table 100-2**).

Table 100-2

Risk Group Classification for Clinically Localized Prostate Cancer

Low risk	PSA <10 ng/mL AND Grade Group 1 AND clinical stage T1-T2a
Intermediate risk	PSA 10 to <20 ng/mL OR Grade Group 2-3 OR clinical stage T2b-c ▪ Favorable: Grade Group 1 with PSA 10 to <20 ng/mL or clinical stage T2b-c and <50%* biopsy cores positive OR Grade Group 2 with PSA <10 ng/mL and clinical stage T1-2a and <50% biopsy cores positive ▪ Unfavorable: Grade Group 1 with PSA 10 to <20 ng/mL and clinical stage T2b-c OR Grade Group 2 with PSA 10 to <20 ng/mL and/or clinical stage T2b-c and/or ≥50%* biopsy cores positive OR Grade Group 3 with PSA <20 ng/mL
High risk	PSA ≥20 ng/mL OR Grade Group 4-5 OR clinical stage T3

*Percent biopsy cores positive is the total number of cores containing cancer divided by total number of cores obtained x 100. This is not the percentage of cancer within a positive core. Regarding assessment of the percent biopsy cores positive for risk stratification, the Panel acknowledges that with the increasing use of pre-biopsy magnetic resonance imaging (MRI) and subsequent targeted biopsies, multiple cores may be obtained from a targeted lesion. Multiple cores from the same lesion should be considered as a single core (ie, for the calculation of percentage cores positive in risk assessment). If all cores are negative, that is considered a single negative core. If one or more cores from the same lesion is positive, that is considered a single positive core, with the highest Gleason score used for risk stratification.

OVERVIEW OF TREATMENT

Treatment modalities of prostate cancer can include surgical removal of the prostate, radiation therapy, hormonal therapy, and other systemic anticancer therapies. Because prostate cancer is fueled primarily by DHT, hormonal therapy will comprise the mainstay of treatment. Only in the advanced setting will cytotoxic chemotherapy and other anticancer therapies be utilized. As well, the option to simply observe the patient is an alternative in certain situations. Prostate cancer can be a very slow-growing disease in certain patients; so with proper selection, these patients may be monitored with no treatment.

For patients diagnosed with cancer confined to the prostate, removal of the prostate, prostatectomy, or radiation to the prostate are the primary treatment options for definitive local therapy. Radiation therapies most commonly used in practice include external beam and brachytherapy. Brachytherapy consists of small pellets of radioactive material that can be placed into the prostate in small-volume disease. These treatments can provide an opportunity for cure in patients with locally confined prostate cancer.[4] Seventy-six percent of patients will be diagnosed in this stage, and have a 5-year survival of nearly 100%.[13] With more advanced cancer, in which there is an increased risk of recurrence, the addition of gonadotropin-releasing hormone (GnRH) therapy to radiation may be necessary. Regional disease similarly has a 5-year survival rate of nearly 100% and is diagnosed in 13% of patients.[13] Only after failure of hormonal therapy will other systemic therapies be used. A number of cytotoxic agents and immunologic and targeted therapies are available for the treatment of castration-resistant metastatic disease. Although only 6% of patients are initially diagnosed with metastatic disease, their 5-year survival is only 30%.[1] Therapy in the different stages of prostate cancer is discussed in more detail subsequently.

RISK FACTORS

CASE 100-1

QUESTION 1: S.J. is a 67-year-old African American male who has never been screened for prostate cancer. He has no comorbidities, does not smoke, and exercises regularly.

What are S.J.'s risk factors for prostate cancer?

Age

Risk factors are important in identifying those males who are most likely to develop prostate cancer and also help identify those who will most benefit from screening. Age is the most important factor, with about half of all cases occurring after the age of 65 years and rarely occurring before age 40 years. Median age at the time of death is 80 years.[1]

Ethnicity

The risk of development of prostate cancer begins to increase after age 50 years in non-Hispanic Caucasian males and after age 40 years in males with African ancestry in the United States and the Caribbean. Those of African ancestry have a 1.8-fold higher incidence of being diagnosed with prostate cancer than do males of European ancestry. Prostate cancer also has one of the largest disparities in death rates, with those of African ancestry having more than a twofold greater risk of dying than do those of European ancestry.[1] However, one study has found that, when controlling for other nonbiologic factors in three different cohorts, African American males did not appear to have lower mortality. All the three groups had equal access to care and received standard treatments for their disease. Further identification of differences between ethnicity and socioeconomic factors and their effects on the incidence and mortality in this population will need to be defined.[14] Males of

American Indian/Alaska Native descent have the lowest risk of developing prostate cancer, followed closely by Asian/Pacific Islander descent, who have the lowest rates of prostate cancer mortality (**Fig. 100-1**).[1]

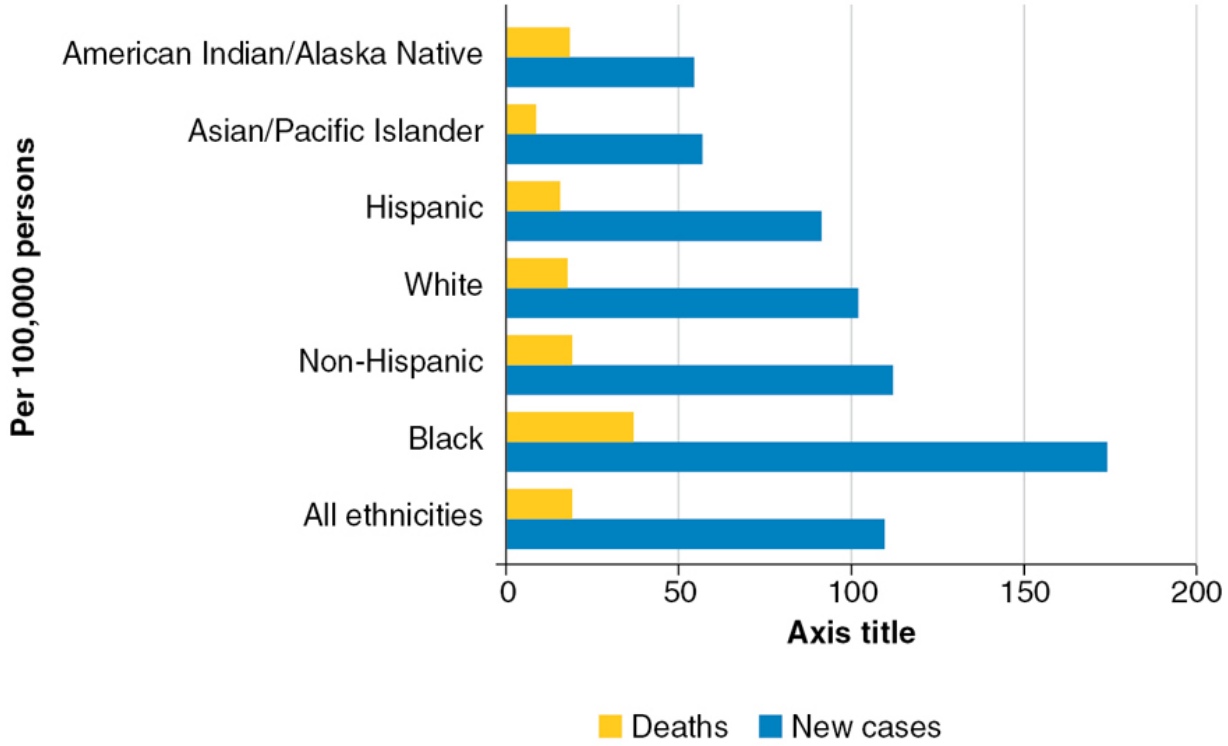

Figure 100-1 Incidence of new cases of prostate cancer by race and age. (From National Cancer Institute: Surveillance, Epidemiology, and End Results Program (SEER). Cancer stat facts—prostate cancer. National Institutes of Health. Accessed January 26, 2021. https://seer.cancer.gov/statfacts/html/prost.html.)

Family History

Family history (FH) confers up to a two- to threefold increased risk if a male's brother or father has been diagnosed by age 60 years. The risk is even higher if two or more first-degree relatives develop prostate cancer. Younger age at diagnosis in a family member is a higher risk than is a family member who is diagnosed later in life.[4]

Genetic Syndromes

Several inherited, or germ line, mutations are associated with an increased risk of prostate cancer. Although these high-risk genetic mutations are relatively uncommon in the overall population, a known FH may indicate the recommendation for genetic counseling and possibly genetic testing.[15,16] Mutations in the inheritable *BRCA 1/2* genes can increase the risk of developing several cancers, including breast, ovarian, and prostate cancer. Germ line *BRCA2* mutations are associated with up to an 8.6-fold increase in the risk of prostate cancer.[17] Moreover, cancers with *BRCA2* mutation are more likely to have an earlier onset, higher incidence of aggressive disease, and shorter survival time.[18] The implications of *BRCA1* on prostate cancer risk are less established, with one report stating a 3.75-fold increase in relative risk, although mutations in *BRCA 1/2* are often considered together.[19]

Males with Lynch syndrome (germ line mutations in *MLH1*, *MSH2*, *MSH6*, *PMS2*, or *EPCAM*) have a two- to fivefold increase in the risk of prostate cancer. However, these cancers act similarly to those cancers without the mutation, so they are not more aggressive or occur at any earlier age.[20]

S.J. has the following risk factors for the development of prostate cancer: ethnicity and age.

Case 100-1, Question 2: S.J. has learned that his 47-year-old brother was just diagnosed with advanced prostate cancer. How has S.J.'s risk changed?

Because S.J. now has a first-degree relative who has been diagnosed with prostate cancer, especially before the age of 60, his risk has increased substantially (two- to threefold).

SCREENING

Case 100-1, Question 3: After S.J.'s brother's diagnosis, he becomes concerned and makes an appointment with his primary care office to discuss screening. Should S.J. begin routine screening for prostate cancer?

Over the past 35 years, 5-year survival rates increased from 68% to 99%, attributed in part to early detection guidelines. There are several guidelines for the screening of prostate cancer, including those of the American Cancer Society,[5] and the American Urological Association (Table 100-1).[21] Historically, males age older than 50 years were encouraged to have a PSA screening yearly. There was a steep rise in the diagnosis of prostate cancer once PSA screening was put into effect in the early 1990s, from >100 cases per age-adjusted 100,000 in 1975 and peaking at 240 cases per 100,000 in 1992. At the time of writing, it is at a rate of 110 cases per 100,000.[1] However, controversy remains among different organizations regarding the appropriate recommendations for PSA screening. Prostate cancer is a relatively slow-growing cancer that may not be life-threatening to some patients and potentially would not need treatment. The lifetime risk of being diagnosed with prostate cancer is 11%, and the lifetime risk of dying of prostate cancer is 2.5%.[22] Because it occurs primarily in older males, a number of males might not develop symptoms of the disease that would cause them to be tested if not for routine screening. These patients could be subject to the risks of screening procedures and possibly treatment of otherwise clinically insignificant disease.

The Prostate, Lung, Colorectal, and Ovarian (PLCO) Screening Trial randomized over 76,000 U.S. males to strict annual PSA and DRE screening or to standard practice. It was found that prostate cancer was identified more often in the annual screening group, but that it did not change the rate of fatal disease.[23] However, a European study that randomized >182,000 males to yearly screening or to no screening found that in the screening group, the relative reduction in risk of death was 21% at a median follow-up of 11 years. To prevent one death from prostate cancer, 1055 males would need to be screened and 37 cancers would need to be

detected.[24] Therefore, it is being recognized that prostate cancer may be overdiagnosed (overdetection), especially at older ages. Overdiagnosis is typically defined as detecting a disease when it would not otherwise have shortened lifespan or resulted in adverse effects.[25] The U.S. Preventive Services Task Force concluded that for every 1000 males between ages 55 and 69 years who were screened, 1.3 deaths from prostate cancer would be avoided over 13 years. There are risks associated with any potential diagnosis, including risks during biopsy such as infection, bleeding, and dysuria, along with risks associated with unnecessary treatment, which need to be taken into account in the risk-to-benefit ratio of screening.[22] These studies highlight the need for selective screening to avoid overdiagnosis and overtreatment while not compromising long-term survival.

Guidelines are relatively consistent in their recommendation that males at ages older than 70 to 75 years do not need to be screened because they have not been diagnosed with cancer at this time, and are more likely to die of unrelated causes before ever having any symptoms in this slow-growing cancer. Guidelines emphasize considering the life expectancy of the patient and not screening those whose expectancy is <10 to 15 years. For those at an elevated risk of developing prostate cancer (eg, family, ethnicity, or other risk factors), it may be beneficial to initiate screening at an earlier age. However, the majority of guidelines advocate that all males should have a discussion with their doctor regarding any risk factors that they have, and together decide whether they should undergo screening and at what age to start, depending on their risk factors, comorbidities, and personal preferences.[5,21,22] For S.J., because of his elevated risk owing to his brother's diagnosis and his ethnicity, it may be considered prudent to begin screening. However, this should be discussed with his doctor to ensure that he recognizes all the benefits and risks of screening.

PROGNOSTIC FACTORS AND RISK STRATIFICATION

CASE 100-2

QUESTION 1: C.W. is a 69-year-old male who began routine screening for prostate cancer with his primary care physician 14 years ago. His PSA history is listed subsequently. His PSA drawn on August 5, 2017, is 6.68 ng/mL. DRE finding is negative. He has an excellent performance status, being fully active and able to carry out all activities without restriction. On physical exam, he is well appearing with no apparent signs of distress. He has no known FH of prostate cancer. When asked about his social history (SH), he said that he drinks socially, with an average of one to two drinks every month, and has never smoked or used illicit drugs. His past medical history (PMH) is significant for hypercholesterolemia, hypertension, and depression.

Medications: atorvastatin, lisinopril, and sertraline; no known allergies

PSA History:	
Date	**PSA Level (ng/mL)**
August 5, 2017	6.68
September 22, 2016	3.11
September 25, 2015	2.52
August 29, 2014	2.46
August 27, 2012	2.27
September 3, 2010	2.02
August 19, 2008	1.98
August 15, 2006	1.82

From the abovementioned assessment, what would have prompted C.W.'s primary care physician to refer the patient to a urologist?

Using prognostic factors to stratify the risk of the cancer recurring is essential to better characterize the cancer and to determine the optimal initial treatment. This is particularly important with a heterogeneous disease such as prostate cancer. Patients with a high

risk of recurrence will need more aggressive treatment, whereas those with low risk can benefit from a more conservative approach. Stage of the tumor, PSA, and grade group are prognostic factors that can be used by the provider to calculate the probability of a patient recurring in the next 5 to 10 years. In addition, germ line and genetic testing are recommended in certain patients to further improve risk stratification and guide treatment decisions. Certain germ line mutations, such as *BRCA2*, are associated with aggressive prostate cancer, indicating the need for a higher risk reclassification.[26] Utilizing these prognostic factors will help the physician determine the best therapies for their patient while maximizing quality of life.

Life Expectancy

There are a number of males who will die with, not of, their prostate cancer. Autopsy data has shown that as many as 7 out of every 10 males who died of various causes had prostate cancer at time of death that was undiagnosed (**Fig. 100-2**).[27,28] Estimation of a patient's life expectancy can help determine the extent of benefit of potential life gained from treatment. Males with short life expectancies are at low risk for developing any symptoms of disease, or morbidity, before their demise from another unrelated event, and therefore will likely not benefit from definitive treatment. Conversely, younger males otherwise in good health are likely to need treatment because they have a longer lifetime in which to develop a recurrence of cancer that can be a cause of morbidity and mortality. Although insurance life expectancy charts (Minnesota Metropolitan or the Social Security Administration Life Insurance Tables) can be used to determine potential life expectancy, it often is a comprehensive clinical determination by the patient's health care team, weighing a number of factors, including their overall health, quality of life, comorbid conditions, and FH, when determining a treatment plan.[4] The Social Security Administration Life Insurance Tables can be found at www.ssa.gov/OACT/STATS/table4c6.html

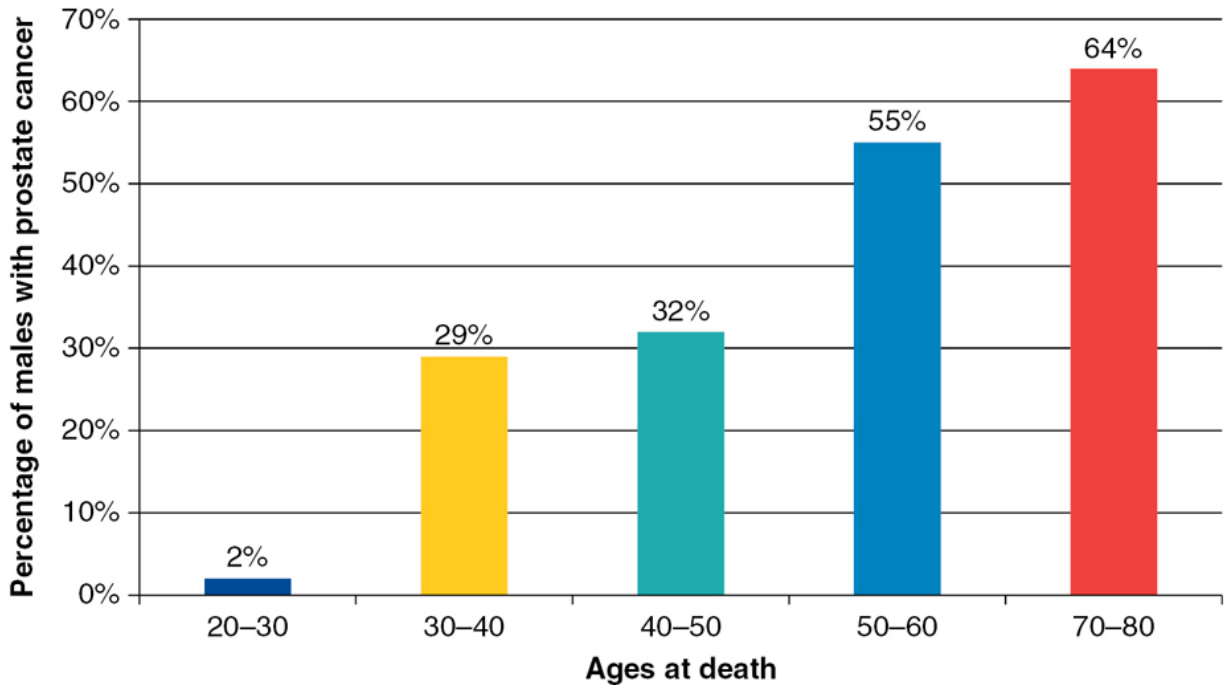

Figure 100-2 Percentage of males found to have prostate cancers at autopsy after dying of unrelated causes in the era before standardized prostate-specific antigen (PSA) testing. (Reprinted with permission from Sakr WA, Grignon DJ, Crissman JD, et al. High grade prostatic intraepithelial neoplasia (HGPIN) and prostatic adenocarcinoma between the ages of 20–69: an autopsy study of 249 cases. *In Vivo*. 1994;8(3):439–443.)

Prostate-Specific Antigen

As previously discussed, serum PSA level is used in screening for prostate cancer detection. It is also a prognostic factor used as an aid to determine treatment because a higher PSA level is associated with an increased risk of more advanced and potential progression of disease. The more prostate cancer cells there are, the more PSA is being made. Being able to determine how fast the level is rising is another way to assess the cancer's ability to potentially recur and progress. However, it is also known that not all prostate cancers will produce elevated PSA levels. Serum PSA is another tool that may help the practitioner assess the risk of recurrence in a specific patient. As mentioned previously, males with PSA levels of 4 to 10

ng/mL have a one in four chance of having prostate cancer; that risk doubles if the level increases above 10 ng/mL.[10]

There have been some developments in PSA testing in an attempt to refine patient selection for further screening and cancer detection. These include different calculations of and adjustments to PSA, such as PSA velocity, percent free PSA, and PSA density. There is a lack of evidence to support the use of these tests in routine practice.[21]

Because C.W. had a PSA level of 3.11 in 2016 and it increased to 6.68 in 2017, there is concern that he may have developed prostate cancer. The Prostate Cancer Prevention Trial (PCPT) found that 15% of males with PSA ≤4.0 ng/mL and a normal DRE were diagnosed with prostate cancer. This percentage doubles with PSA levels between 4 and 10 ng/mL.[11]

Case 100-2, Question 2: C.W. is referred to the urologist for further evaluation. What additional diagnostic procedures can be done to definitively diagnose prostate cancer? What assessments can be done from the procedure for better prognostication of the disease?

Tumor Staging

The AJCC developed a staging system for newly diagnosed prostate cancer. This AJCC TNM staging system classifies the extent of the tumor according to the size of the tumor (T), the extent of lymph node involvement (N), and the absence or presence of distant metastases (M).[10] In general, if the cancer remains within the prostatic capsule, it is considered a localized disease. If it has spread outside of the capsule or has invaded the adjacent structures, it is locally advanced or regional, and the cancer is considered metastatic if it has spread to other parts of the body.

Grade Group and Gleason Score

A Gleason pattern is the histologic grading of the tumor biopsy. There are five distinct patterns of growth from well (1) to poorly (5)

differentiated with progressive loss of glandular formation (**Fig. 100-3**).[29] Well-differentiated cancer cells are those that are most similar to the normal prostate cells and tend to grow and spread at a slower rate than do poorly differentiated tumor cells that are more aggressive. Up to 50% of prostate tumors demonstrate more than one histologic pattern.[30] By assessing several of the biopsy samples to find the most common growth patterns, the aggressive behavior of the tumor can be more accurately estimated. The Gleason score is calculated by adding the most common to the second most common growth patterns found in the core biopsies. The Gleason score was refined and incorporated into the more recently adopted grade group system, of which there are five categories. Grade group 1 designates a well-differentiated, less aggressive tumor, whereas a grade group 5 is considered a poorly differentiated, more aggressive tumor.[31] An aggressive tumor is one that will grow faster and have a higher risk of metastasizing, increasing the likelihood of recurrence after localized treatment. Grade group system is one of the integral evaluations for accurate risk stratification.

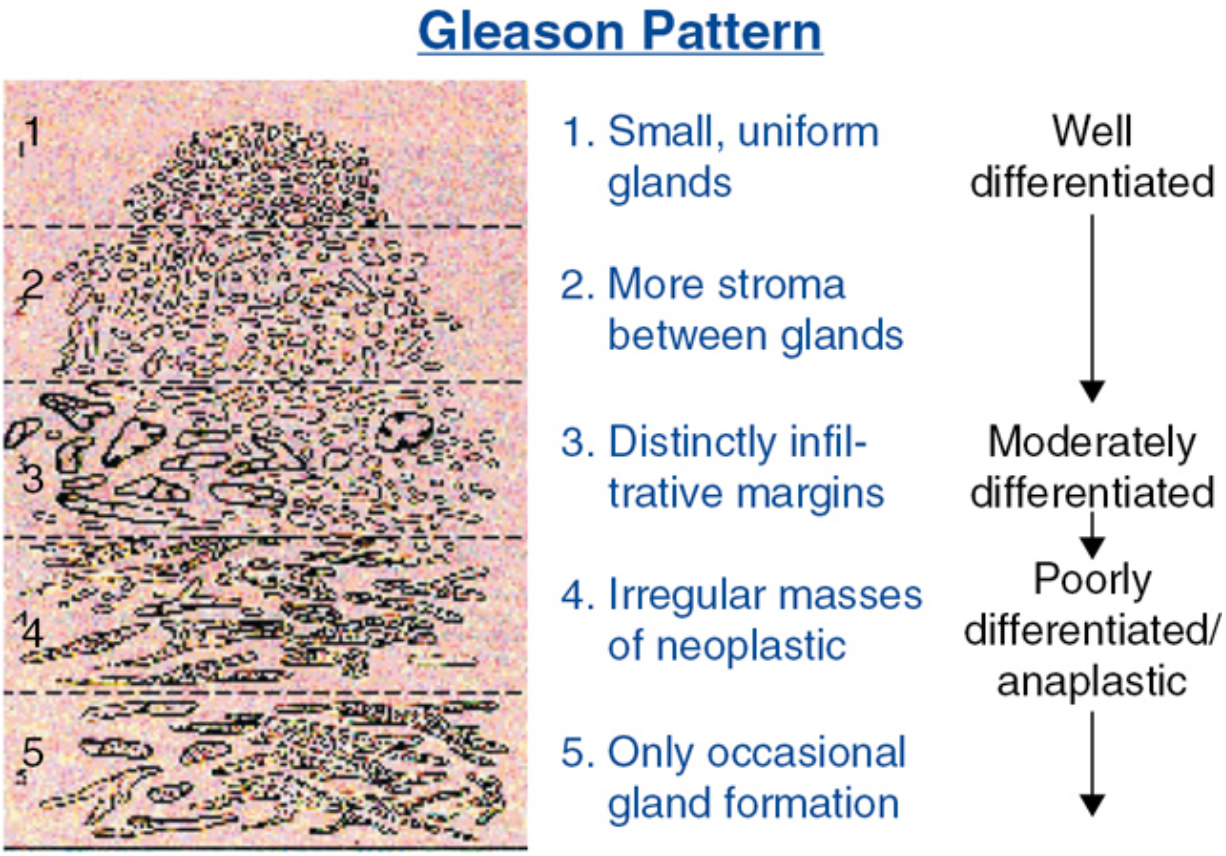

Figure 100-3 Gleason histologic grading of prostate cancer demonstrating progressive loss of glandular formation with increasing score. (Reprinted with permission from Zelefsky MJ, Morris MJ, Eastham JA. Cancer of the prostate. In: DeVita VT, Lawrence TS, Rosenberg SA, eds. *DeVita, Hellman, and Rosenberg's Cancer: Principles and Practice of Oncology*. 11th ed. Wolters Kluwer; 2019:1091.)

Germ Line Genetic Testing and Tumor Molecular Analysis

Advances in DNA sequencing have expanded the understanding of genetics in prostate cancer. Certain germ line genetic mutations have been associated with more aggressive prostate cancer and shortened survival. This is most recognized in germ line mutations in *BRCA2* and has been implicated in other DNA repair gene mutations. The frequency of mutations in DNA repair genes, also

known as *homologous recombinant repair* (HRR) *mutations*, is higher in metastatic prostate cancer, but is overall associated with more aggressive disease and poor outcomes.[32] Because of the potential implications on prognosis and risk stratification, genetic counseling and testing is recommended by several guidelines in early-stage prostate cancer according to FH, personal history, and classification or stage of cancer at diagnosis. Some of the more significant factors that may indicate the need for genetic counseling and testing include FH of hereditary syndromes or certain other cancers, strong FH of prostate cancer, Ashkenazi Jewish ancestry, and localized disease with aggressive prognostic factors. Later in metastatic prostate cancer, HRR mutations are more common and can impact clinical decisions and qualify patients for certain therapies. Therefore, genetic testing is generally recommended in all patients with metastatic prostate cancer.[33]

Molecular biomarker testing of the tumor tissue can provide further characterization of clinically localized cancer and can aid in clinical decision-making. Some tests may be particularly useful when considering active surveillance or treatment intensification in localized prostate cancer. It may be considered in low-stage, localized prostate cancer patients when it may aid in treatment decisions. Several of these molecular biomarker tests, including Decipher® (GenomeDx Biosciences, Vancouver, BC, Canada), Oncotype DX® (Genomic Health, Redwood City, CA) prostate assay, Prolaris® (Myriad Genetics, Salt Lake City, UT), and ProMark® (Metamark Genetics Inc., Waltham, MA), have been evaluated and are available for use. They have not been prospectively validated to assess the complete impact on long-term outcomes and are not yet the standard of care.[34]

If genetic testing or molecular biomarker testing is available, it can provide further information regarding the prognosis, risk stratification, and treatment selection of patients with clinically localized prostate cancer.

Risk stratification tools that incorporate stage, PSA level, and grade group have been developed and validated because they identify those males who are associated with an increased risk of

recurrence and worse outcomes after localized treatment. Patients with localized prostate cancer who are yet to receive treatment can be grouped as low, favorable and unfavorable intermediate, and high risk to be used by providers, along with other factors such as genetic testing, life expectancy, and overall health of the patient, in the selection of initial treatment (Table 100-2).[26,35]

A TRUS-guided needle biopsy can be done to definitively diagnose prostate cancer. The biopsy specimen can be used to determine the prognostic factors of clinical stage and the grade group.

Case 100-2, Question 3: C.W.'s biopsy revealed a grade group 1, stage T1c (no suspected nodal or distant metastases) prostate cancer in 3 of 10 cores. Based on C.W.'s prognostic factors, what is C.W.'s risk group?

C.W. has stage T1cN0M0 prostate cancer with a grade group 1 and a PSA <10 ng/mL. With these prognostic factors and with 3 of 10 positive cores, he is considered to have low-risk prostate cancer.

LOCALIZED DISEASE

Observation Versus Active Surveillance

Case 100-2, Question 4: C.W. consulted with a medical oncologist about his treatment options for low-risk prostate cancer. The oncologist explained that C.W. is an overall healthy patient with a long life expectancy and that his prostate cancer is relatively slow growing. What is C.W.'s conservative option for the management of his prostate cancer?

Studies have aimed to identify those select males who will have a good outcome with a very conservative approach of no immediate, definitive intervention for their cancer. This is because we are now seeing what some call an overtreatment of prostate cancer. Overdiagnosing, as discussed earlier, plays a role, with some

models estimating between 23% and 42% of all U.S. screen-detected cancers are being overtreated.[36] This approach of not treating the cancer immediately has subtle distinctions, according to differences in patient status.

Observation (or watchful waiting) involves no cancer intervention, such as additional biopsies, scans, surgery, or treatment, but simply monitors the patient with the plan to only deliver palliative therapy if symptoms develop. This is recommended for patients with a life expectancy ≤5 years because prostate cancer treatment does not improve survival within 5 years. The goal of observation is to avoid treatment and its potential side effects in order to maintain the patient's quality of life. This is an appropriate strategy for elderly patients or patients that have comorbidities that may threaten mortality more than the mortality risk from prostate cancer.[26]

Active surveillance is different from observation because these males are actively monitored with routine PSA levels and, potentially, biopsies with the expectation of intervention if it looks like the cancer is progressing with a goal of deferring side effects from treatment without missing the opportunity for cure. For this reason, it is preferred in patients with low-risk prostate cancer. It is also an option in patients with favorable intermediate-risk disease.[26] A study of almost 1000 males with favorable or intermediate-risk prostate cancer on active surveillance were followed up for a median of 6.4 years (range, 0.2–19.8 years). They were offered treatment if their PSA doubled in <3 years, if their Gleason score was higher based on another biopsy, or if they had clinical progression. Of those 993 study participants, 15% died, but only 15 patients (1.5%) died from prostate cancer. There were an additional 13 patients (1.3%) who developed metastases, but only four had died at the time of analysis. At 5, 10, and 15 years, 75.7%, 63.5%, and 55% of patients, respectively, were untreated and continued surveillance.[37] In another study of >5500 males with low-risk and favorable intermediate-risk prostate cancer treated with brachytherapy and then active surveillance, 605 males had died, but only 5.6% of those deaths were because of prostate cancer.[38] These studies illustrate the potential to delay therapy in selected males without compromising

survival. The decision of observation or active surveillance should be made after a full discussion between the patient and the physician of the advantages and disadvantages of this approach.

Because C.W. has low-risk prostate cancer and an excellent performance status without precluding comorbidities, giving him a long life expectancy, he would be eligible for active surveillance. He would not be a candidate for observation given his age and long life expectancy.

Definitive Local Therapy

Treatments for early-stage disease can include radiation, mainly in the form of either brachytherapy or external beam radiation therapy (EBRT), and radical prostatectomy. These localized treatments are used because the cancer is thought to still be confined to the prostate. Choice of therapy is dependent on risk stratification, which takes into account the extent of disease, pathologic stage, and PSA, along with life expectancy, patient preference, and potential comorbidities that may cause complications and impact treatment outcomes. If treatment is successful and if the correct patients are selected, these local therapies can potentially provide a cure for the disease.

SURGERY

Radical prostatectomy is the surgical removal of the prostate gland and possibly some surrounding tissue. It is generally recommended only for patients with clinically confined prostate cancer with no comorbidities precluding their ability to undergo an operation. A study using the Surveillance, Epidemiology, and End Results (SEER) Medicare database looked at outcomes after surgery among hospitals and surgeons. In a study of 11,522 males between 1992 and 1996, it was found that postoperative complications correlated with the volume of procedures performed by the surgeon and the volume done at the institution. Postoperative morbidity was lower in very high-volume hospitals compared to low-volume hospitals (27%

vs 32%; *P* = .03) and was also lower when performed by high-volume surgeons as compared to low-volume surgeons (26% vs 32%; *P* > .001). There was no link between surgeon/institution and death.[39] Another study found that surgeon experience was linked to a lower risk of recurrence (*P* > .001) when adjusted for tumor characteristics and year of surgery in patients who received no other therapy. Five-year probability of recurrence was 17.8% in the early phase of career (10 prior operations) compared to 10.9% later on (>250 operations).[40] These findings confirm that experience is a critical factor in the success of radical prostatectomy. Surgery can be done as either an open or a laparoscopic radical prostatectomy, and can also include the removal of surrounding lymph nodes if there is suspicion of nodal metastases. Laparoscopic removal of the prostate, with or without robotic assistance, is less invasive and usually a shorter hospital stay and a quicker recovery.

Additional information from the surgery can provide more accurate prognostic information on the grade or any extension into the surrounding tissue or lymph nodes. This information is used to determine whether further treatment is necessary. In addition to providing more accurate prognostic information, radical prostatectomy also has the benefit of being a short treatment with a hospital admission typically being 1 day. It does, however, have the risks of erectile dysfunction, urinary incontinence, and morbidities associated with any major surgery. Because of these risks, radical prostatectomy is indicated for intermediate-risk or high-risk patients with a life expectancy >10 years.[26]

RADIATION THERAPY

Radiation therapy uses high-energy beams in the case of EBRT, or radioactive particles in the case of brachytherapy, to kill cancer cells. With brachytherapy, the radiation sources are placed directly into the prostate for a direct action with minimal effect to surrounding tissue. This form of radiation is given as either low dose or high dose, and is indicated as monotherapy for lower and favorable intermediate-risk cancers or can be given as an adjunct to EBRT in unfavorable

intermediate- and particularly in higher risk cancers. Brachytherapy has the advantage of a short, 1-day course of therapy and minimal risk of incontinence and erectile dysfunction, but it can cause acute urinary retention.[41]

Current EBRT techniques use three-dimensional conformal radiation therapy (3D-CRT) to deliver radiation under the guidance of computer-generated images of a patient's anatomy. Intensity-modulated radiation therapy (IMRT) is the second iteration of 3D-CRT that uses various intensities of radiation according to the needs of the treatment area. Image-guided radiation therapy (IGRT) is a 3D-CRT that more accurately localizes the treatment area. Both IMRT and IGRT techniques are the standard of care for EBRT treatment that allows for higher doses of radiation to be delivered more precisely to lower the risk of adverse effects. Because of the proximity of the prostate to the bladder and rectum, treatment with EBRT can cause rectal urgency and increased bowel frequency, urinary frequency and incontinence, and erectile dysfunction. Although these symptoms are most often experienced short term and the risk is lessened with newer techniques, they can persist for the long term in a low percentage of patients.[42] Unlike radical prostatectomy, EBRT avoids surgery and anesthesia complications, such as bleeding, myocardial infarction, or pulmonary embolism. EBRT is an option for low-risk, intermediate-risk, and in higher risk cancers. It is typically combined with a short course of ADT for unfavorable intermediate risk and a longer course with ADT in high risk cancers (see section Androgen Deprivation Therapy).[43]

Other modalities of radiation therapy, such as proton beam and stereotactic body radiation, have been used in the treatment of localized prostate cancer. However, their benefits over the current standards have not been established in the first-line setting of definitive localized treatment.[44]

Treatment outcomes of patients with localized prostate cancer treated with radiation, surgery, or active surveillance/observation have been compared in large prospective, population-based studies. A randomized control trial of 1643 males compared radical prostatectomy, EBRT, and active surveillance for treatment of

clinically localized prostate cancer over a median follow-up of 10 years. The primary end point was cancer-specific mortality, of which there were 17 overall: 8 in the active monitoring group (1.5 deaths per 1000 person-years), 5 in the surgery group (0.9 per 1000 person-years), and 4 in the radiotherapy group (0.7 per 1000 person-years). There also was no significant difference in cancer-specific mortality (*P* = .48) or in all-cause mortality (*P* = .87). A higher rate of disease progression was seen with active surveillance than with prostatectomy or EBRT.[45] A study by Barocas et al, compared 2550 males with localized prostate cancer who were treated with radical prostatectomy, EBRT, or active surveillance. It found that radical prostatectomy was associated with a greater decrease in urinary incontinence and sexual function than with EBRT or active surveillance, but was associated with better urinary irritative symptoms than with active surveillance.[46] Several other prospective studies investigating patient-reported outcomes have found differences in quality of life with the various treatment modalities.[47,48] Physicians must compare the advantages and disadvantages of each treatment along with patient-specific factors to determine the most appropriate therapy.

Androgen deprivation therapy

Androgen deprivation therapy (ADT) is the suppression of androgen production or action. It can be used in the localized prostate cancer setting in combination with radiation therapy for unfavorable intermediate-risk patients and is used as a standard in combination with radiation in higher risk patients. ADT can be done either through orchiectomy, because ~90% of androgens will come from the testes and is called *surgical castration*, or by adding a GnRH analog, called *medical castration*. Both should decrease the body's testosterone production to castrate levels, usually <50 ng/mL. Because both methods are equally effective, most males will start GnRH therapy; however, orchiectomy can be useful for immediate decreases in testosterone when patients present with highly symptomatic disease or when adherence, cost, or availability is prohibitive. **Table 100-3**

includes the GnRH agonists, which include leuprolide, goserelin, histrelin, buserelin, and triptorelin as well as one GnRH antagonist, degarelix. In addition to the injectable GnRH analogs, an oral formulation of a GnRH antagonist has most recently been approved. Thus far, it has only been studied in patients with advanced or relapsed prostate cancer, and so its approval is currently limited to this setting.[49]

Table 100-3
Androgen Deprivation Agents

Agent	Route	Dose
GnRH Agonists		
Leuprolide (Eligard®)	Subcutaneous	7.5 mg every month 22.5 mg every 3 months 30 mg every 4 months 45 mg every 6 months
Leuprolide (Lupron Depot®)	Intramuscular	7.5 mg every month 22.5 mg every 3 months 30 mg every 4 months 45 mg every 6 months 3.75 mg
Triptorelin (Trelstar® or Trelstar Mixject®)	Intramuscular; suspension (reconstituted)	3.75 mg every 4 weeks 11.25 mg every 12 weeks 22.5 mg every 24 weeks
Goserelin (Zoladex®)	Subcutaneous implant	3.6 mg every 28 days, 10.8 mg every 12 weeks
Histrelin (Vantas®)	Subcutaneous implant	50 mg every 12 months
Buserelin (Suprefact®)	Subcutaneous	500 µg every 8 hours for 7 days. Maintenance 200 µg once daily
Buserelin (Suprefact Depot®)	Subcutaneous implant	6.3 mg every 2 months 9.45 mg every 3 months
GnRH Antagonist		

Agent	Route	Dose
GnRH Agonists		
Degarelix (Firmagon®)	Subcutaneous	Loading dose: 240 mg administered as two 120 mg injections Maintenance dose: 80 mg every 28 days (beginning 28 days after initial loading dose)
Relugolix (Orgovyx®)	Oral	360 mg once on day 1, followed by 120 mg once daily
First-Generation Antiandrogens		
Bicalutamide (Casodex®)	Oral	50 mg once daily (with GnRH analog) 150 mg once daily (monotherapy)
Nilutamide (Nilandron®)	Oral	300 mg once daily × 30 days, followed by 150 mg once daily
Flutamide (Eulexin®)	Oral	250 mg three times daily

GnRH, gonadotropin-releasing hormone.

GnRH agonists work by binding to GnRH receptors to suppress luteinizing hormone (LH) and follicle-stimulating hormone (FSH) production in the pituitary, decrease testicular testosterone and, subsequently, DHT. They bind to the GnRH receptors and initially cause a rise in LH and FSH and a surge in testosterone for up to a week until the continuous pituitary overstimulation eventually downregulates GnRH receptors and decreases hormone levels (**Fig. 100-4**). This initial, transient surge in testosterone, called a *tumor flare*, can negatively impact patients presenting with symptoms, including bone pain and bladder obstruction. The flare can be prevented with the addition of antiandrogen therapy for a short course of at least 7 days. Because GnRH antagonists directly block the receptors, there is an immediate decrease in LH and FSH production and subsequent testosterone suppression, avoiding a tumor flare and the need for antiandrogens, which may be most useful in symptomatic patients who would have experienced an increase in symptoms during this period.[50]

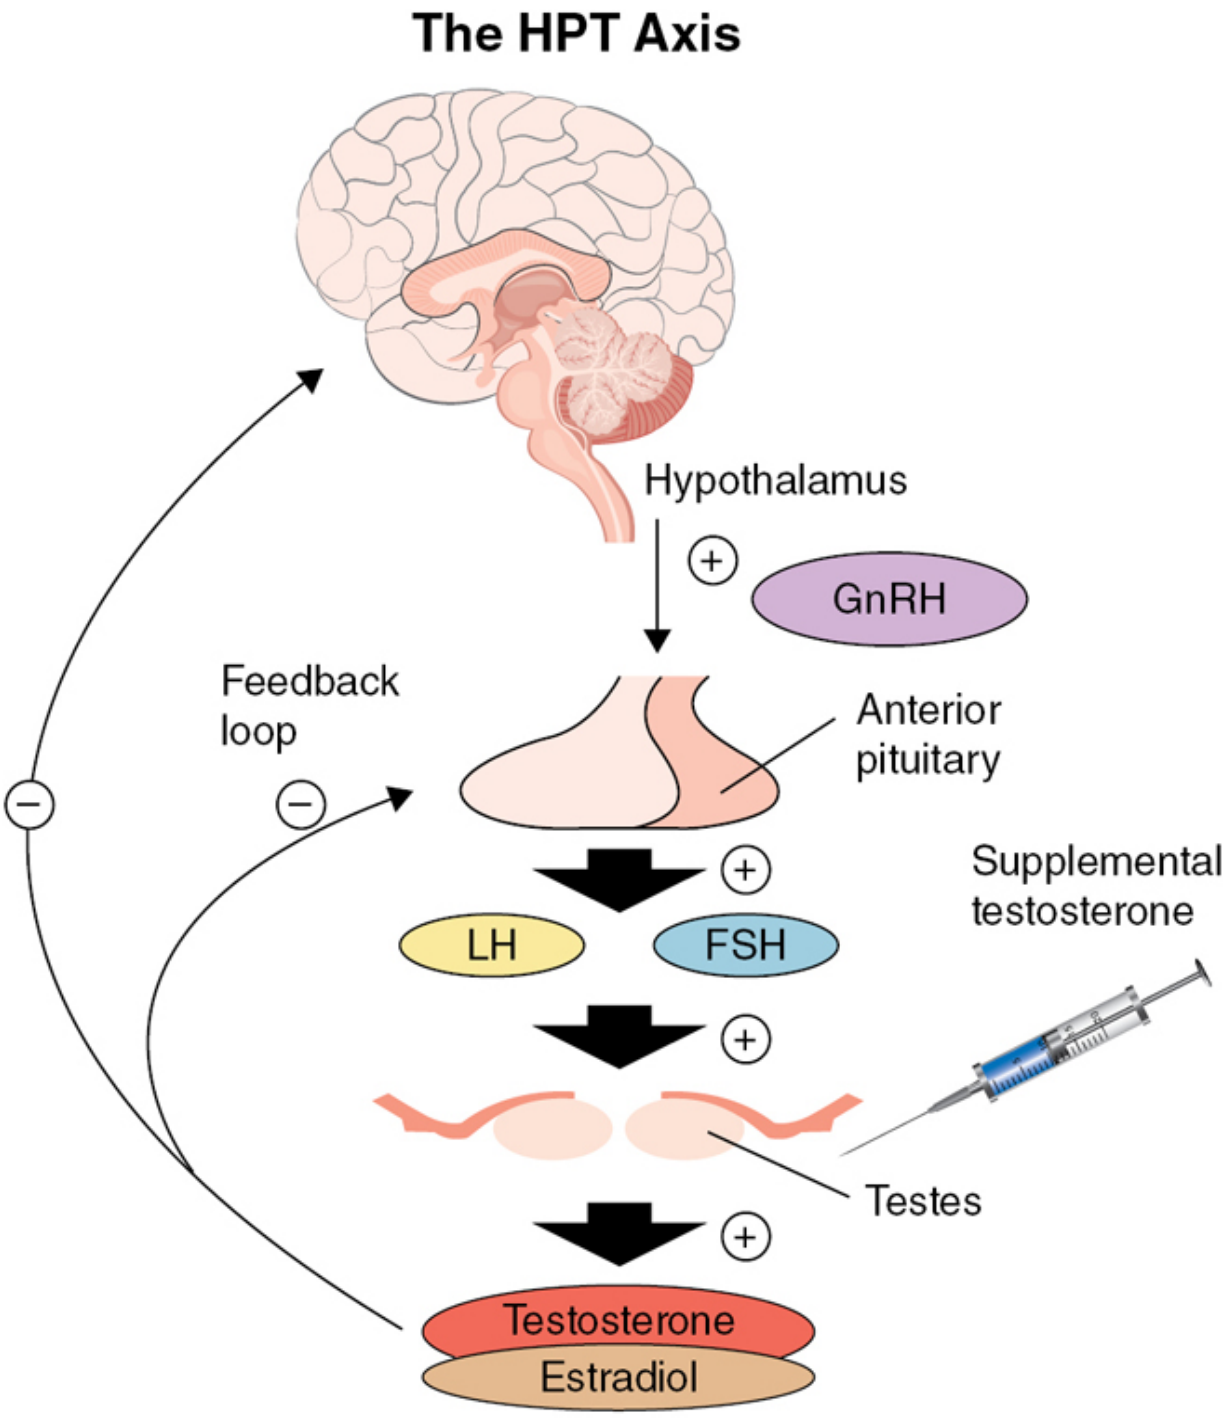

Figure 100-4 The HPT axis is continuously stimulated by GnRH agonists to suppress testosterone through negative feedback. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HPT, hypothalamic–pituitary–thyroid; LH, luteinizing hormone.

Antiandrogens used in this setting are androgen receptor (AR) blockers that work by binding to ARs to competitively inhibit their interaction with testosterone and DHT. These oral medications include flutamide, nilutamide, and bicalutamide. The combination of castration with a GnRH agonist or an orchiectomy and an antiandrogen is called a combined androgen blockade (CAB). In addition to its use to prevent tumor flare or in combination with EBRT for definitive local treatment, CAB can possibly be used later in the treatment of recurrent disease.[51]

Adding ADT to radiation improved cancer outcomes, including survival, in several clinical trials of males with intermediate-risk prostate cancer, and is an option for some patients, particularly those deemed unfavorable intermediate risk.[43] These trials support the use of a short-term course of ADT of 4 to 6 months when added to radiation in unfavorable intermediate risk patients.[52,53] In high-risk patients, combining ADT with radiation therapy improved survival, with studies favoring long-term ADT (2–3 years) over short term (4–6 months). The addition of ADT to radiation is thought to have an additive synergistic cytotoxic effect on cancer cells that can possibly reduce the size of the prostate and the amount of radiation needed.[54] For this reason, ADT is often initiated up to 2 months before radiation. Androgen deprivation monotherapy, without concomitant radiation, has not been shown to be beneficial in patients with localized prostate cancer.[55] Neoadjuvant or adjuvant ADT does not give added benefit with radical prostatectomy.[56]

Traditionally, studies in the treatment of localized prostate cancer with radiation therapy plus ADT were completed using CAB for the entire ADT portion of treatment. However, it is still not proven in randomized trials if the use of CAB is beneficial over castration alone in this setting. Antiandrogen monotherapy is less effective than is medical/surgical castration and is not generally recommended for use in the treatment of prostate cancer.[56]

Using ADT to disrupt the production of testosterone and DHT can cause a range of symptoms that can impact the quality of life, particularly in patients using ADT for prolonged periods. These side effects include hot flashes, decreased libido, erectile dysfunction,

gynecomastia, behavioral changes, and burning at the injection site. Additional concerns of therapy with ADT are discussed further in this chapter.

Case 100-2, Question 5: C.W. is elected to proceed with active surveillance. His medical oncologist had scheduled appointments and PSA checks every 6 months and DREs every 12 months. His results are as follows:

Date	PSA Level (ng/mL)	DRE
January 13, 2018	7.16	
July 12, 2018	7.74	Negative
January 3, 2019	8.08	
July 10, 2019	8.75	Negative
January 30, 2020	10.70	
July 2, 2020	11.70	Negative

C.W.'s PSA continued to rise; however, his overall health remained excellent, and he did not have any symptoms from his disease. C.W. began to get anxious, and the medical oncologist decided to do a repeat biopsy to reassess the tumor and treatment plan. The results revealed a grade group 3 in 4 of 12 cores. What are the possible treatment options for C.W.?

C.W. now has T1cN0M0, grade group 3, PSA 11.7 ng/mL prostate cancer, placing him in the unfavorable intermediate-risk group. His options for definitive local treatment are radical prostatectomy or EBRT plus ADT with the possibility of adding brachytherapy. Because of the results of several trials investigating the use of ADT with radiation in intermediate-risk patients,[52,53,57,58] EBRT would be given with a short course of 4 to 6 months of ADT.

RECURRENCE AND PROGRESSION

CASE 100-3

QUESTION 1: Patient H.L. is a 63-year-old male with a clinical stage T1cN0M0, PSA 9.2 ng/mL, grade group 3 prostate cancer. His PMH is unremarkable, and he has an excellent performance status. He has no known allergies and is not on any medications. His labs are not clinically significant other than his PSA level. When presented with his options, H.L. decided to undergo a radical prostatectomy for definitive local treatment, which revealed a pathologic stage T2cN0M0. He was monitored after surgery, and after 9 months had no symptoms from the procedure or the disease. His PSA was checked twice after surgery and was 0.38 ng/mL and, more recently, 1.2 ng/mL. The medical oncologist believes that the cancer is still present, but does not think there is any indication of disseminated disease.

What type of cancer progression does H.L. have?

For patients who have definitive local treatment with either radiation or surgery, about 25% to 33% of patients will experience a recurrence of their cancer. After the completion of local therapy, patients are monitored by periodically checking PSA for the detection of biochemical recurrence, which is recurrence of disease as indicated only by rising PSA with no other signs or symptoms of disease. The threshold for PSA recurrence is dependent on the initial treatment given. Because a radical prostatectomy involves the removal of all prostate tissue, serum PSA after the procedure should become undetectable. A PSA level of ≥0.2 ng/mL following a radical prostatectomy is considered a biochemical recurrence. Risk factors for the development of a recurrence after radical prostatectomy are the Gleason score, positive surgical margins, and elevated postoperative PSA levels.[59] A biochemical recurrence after EBRT is defined as a rise in PSA level by ≥2 ng/mL above the nadir, or lowest achieved PSA, according to the Phoenix criteria revised by the American Society of Radiation Oncology (ASTRO).[60] Risk factors for recurrence after EBRT include large volume of disease, short time to PSA recurrence, invasion of extraprostatic organs, and a high Gleason score.[61] H.L. is not symptomatic, and his only evidence of disease is his elevated PSA that never normalized after prostatectomy. He has biochemically recurrent prostate cancer.

Case 100-3, Question 2: What is the most appropriate treatment for which H.L. may be eligible?

A biochemical recurrence can indicate that a patient has disease progression. A patient thought to have local recurrence may be eligible to again receive local therapy, called *local salvage therapy*, providing a chance for a cure or a delay in progression. A patient with a biochemical recurrence after a radical prostatectomy with no indication of distant metastases may be a candidate for salvage radiation therapy with or without ADT.[62] Conversely, a patient initially treated with radiation therapy may be a candidate for salvage prostatectomy.[63] In addition to salvage prostatectomy, cryotherapy, which is a procedure that freezes cancer cells, and brachytherapy, if EBRT was first used, are also salvage therapy options post the radiation therapy. Careful consideration of the characteristics of both the disease and the patient must be assessed using imaging, biopsy, and other prognostic tools to determine the appropriateness for salvage therapy.

In patients with clinical features suggesting that the disease is no longer confined to the prostate, called *disseminated prostate cancer*, systemic therapy is indicated. Because prostate cancer continues to be hormone driven, ADT is the initial standard treatment in recurrent prostate cancer. At this point in the disease, patients are considered castrate sensitive, because their cancer is still being suppressed by the lowering of testosterone to castrate levels with ADT. ADT is palliative, but it can control or delay symptoms and complications, improving patient quality of life.

Because the benefit of ADT for biochemical recurrence is still not fully known, when to initiate ADT is still not clear. Observation until evidence of progression is an option; however, patients with rapidly progressing disease, as indicated by the presence of symptoms, an elevated PSA, or a rapid PSA velocity with a long life expectancy, should initiate ADT earlier. With long-term use of ADT, cost and the extensive side effect profile may be limiting and will impact the quality of life for some patients. Intermittent ADT, once there is

response to treatment, rather than continuous administration, is an approach that can minimize side effects and improve quality of life in this setting. With this approach, patients continue ADT until maximal PSA response and then temporarily stop ADT until a set PSA threshold is reached, at which point ADT is reinitiated.[64] The full benefit of intermittent ADT is still not known. A trial done by Crook and colleagues assigned 1386 males with rising PSA after radiation therapy to either intermittent ADT or continuous ADT. The intermittent ADT approach was noninferior in terms of OS (8.8 vs 9.1 years; heart rate [HR] 1.02, 95% confidence interval [CI] 0.86–1.21), but more patients in this group died from prostate cancer (120/690 vs 94/696). The trial demonstrated an improvement in quality of life with intermittent ADT; however, more research must be done to determine the true impact on survival. This approach may be considered for well-informed patients without metastatic disease.[65] The duration of response from ADT varies, but eventually the cancer becomes resistant to ADT and most patients progress.

At this point in the disease, H.L. has recurrent prostate cancer without evidence of disseminated disease. Because it is thought that the disease is a local recurrence, he may still have an opportunity for a cure with local salvage therapy.

Nonmetastatic Castration-Resistant Prostate Cancer

Case 100-3, Question 3: H.L. undergoes local salvage therapy with EBRT and ADT for 6 months. His PSA is monitored after salvage therapy, and it continues to be elevated. Given the rapid rise in PSA, the medical oncologist recommends starting H.L. on systemic therapy with ADT immediately. H.L. initiates treatment with leuprolide 22.5 mg intramuscularly (IM) every 3 months and his labs are checked at every appointment. Pertinent labs during his treatment course of leuprolide are as follows:

Date	PSA Level (ng/mL)	Testosterone (ng/dL)
April 27, 2019	2.56	

July 9, 2019	2.36	
October 17, 2019	2.31	<50
January 23, 2020	2.57	
April 19, 2020	3.08	<50
July 10, 2020	3.74	
October 2, 2020	4.92	<50

H.L. continues to be in good physical health other than experiencing mild depression and three to four hot flashes a day. He is anxious about the persistent rise in his PSA. A computed tomography (CT) scan and bone scan were done, and the findings show no evidence of metastatic disease. How has H.L.'s cancer progressed? What should H.L.'s medical oncologist do next?

If a patient has a rising PSA level while on ADT, a testosterone level should be rechecked to make sure it is below castrate levels. If it is not, then ADT is not adequately blocking the production of androgens, and a change in medication or an orchiectomy is usually recommended. If the testosterone level is <50 ng/mL, the patient is confirmed to be castrate resistant, and additional systemic treatment will be necessary. Imaging tests can be used to identify the presence or absence of distant metastases, the results of which will determine the appropriate treatment course. If a patient with CRPC has no evidence of metastatic disease, then the cancer is classified as nonmetastatic CRPC.

Despite the fact that the cancer is now labeled castration resistant, it is still very dependent on the androgen pathway, and can continue to be targeted throughout the disease. Patients who have nonmetastatic CRPC will typically be responsive to secondary hormonal manipulations combined with continued GnRH analog. Further research into therapeutic targets of the androgen pathway has led to the development of second-generation AR inhibitors. Similar to the first-generation antiandrogens (see Table 100-3), these novel agents inhibit the AR, but are considered more potent and efficacious. OS benefits have been demonstrated in clinical trials

with these new agents in the setting of nonmetastatic CRPC. The patients in these trials were considered high risk for progression, as indicated by a short prostate-specific antigen doubling time (PSADT ≤10 months), or the rate/velocity at which the PSA doubles; therefore, these agents are often initiated once patients meet these criteria. If patients progress on a next-generation AR inhibitor and are confirmed to still have nonmetastatic CRPC, then other secondary hormone manipulation strategies can be implemented. These strategies have not shown a survival benefit, but may slow the progression of the disease and symptoms. They include first-generation antiandrogens, androgen withdrawal, ketoconazole, and other secondary hormone manipulations discussed subsequently.

H.L. now has nonmetastatic CRPC confirmed by the rise in PSA despite testosterone below castrate level on ADT, with no evidence of metastatic disease on scans. The next step for H.L. would be to continue leuprolide and add a second-generation antiandrogen when he is thought to be at high risk for progression (ie, short PSADT).

METASTATIC DISEASE

When metastatic disease occurs, performance status and extent of disease as determined by imaging should be evaluated because these factors will determine treatment options and outcomes. Both germ line and somatic, or acquired, genetic mutations in *HRR* genes can have clinical implications in metastatic prostate cancer. Genetic testing is recommended in this setting to further characterize the disease and identify possible treatment options. In addition, a discussion with the patient is necessary regarding the goals of treatment because it is focused on palliation and improvement in quality of life rather than the chance for cure as it is with treatment for localized disease. Metastatic disease is most likely to be seen in the bones, lung, and liver. Symptoms are more common in metastatic disease and are often related to the sites of metastases.

Metastatic Castration-Sensitive Prostate Cancer

Patients who are first diagnosed with metastatic prostate cancer, or patients who develop metastatic disease after definitive local therapy, are considered castration sensitive, or castration naive because they have progressing disease but have not yet received ADT and do not have castrate levels of testosterone. Treatment for these patients includes ADT as the backbone of therapy, just as it does in earlier stages when ADT is indicated for progression or recurrence, because the disease continues to be hormone dependent. The choices for ADT include GnRH antagonists, GnRH agonists with an antiandrogen for patients at risk for tumor flare symptoms, and, less commonly, orchiectomy. The addition of chemotherapy and androgen-directed therapies to initial ADT in patients with castration-sensitive prostate cancer has shown a survival benefit, and are viable treatment options. Docetaxel was one of the first and only chemotherapies that had demonstrated a survival benefit in metastatic CRPC. More recently, strong evidence has supported its use as combined therapy with ADT for the initial treatment of patients with castration-sensitive prostate cancer.[66,67] There are several next-generation androgen-directed therapies approved in this setting as well. There is yet to be a clear consensus on initial treatment selection or sequencing of these treatment options. Careful considerations of a medication's administration, treatment duration, toxicity profile, and cost, along with a patient's overall health, comorbidities, and volume of disease should be taken into account during treatment selection.[68]

Metastatic Castration-Resistant Prostate Cancer

There are a number of different treatment options that can be used in metastatic CRPC, including chemotherapy, immunotherapy, androgen pathway–directed therapy, and other targeted therapies. Males who are in good health and have asymptomatic disease may be treated with sipuleucel-T, an immunotherapy. For castrate-resistant disease that is symptomatic and rapidly progressing,

cytotoxic chemotherapy would generally be considered. Newer androgen-directed therapies can be given before or after chemotherapy. If genetic testing shows mutations in *HRR* genes, then the use of poly-ADP ribose polymerase (PARP) inhibitors is also an option. Again, optimal sequencing of these agents is still not fully elucidated; however, patients with poor performance status, or a need to delay cytotoxic chemotherapy, can benefit from receiving the relatively tolerable androgen-directed therapies sooner rather than later. A discussion regarding the benefits of each therapy, along with potential adverse effects, is important in deciding if and when these therapies should be implemented.

TREATMENT OPTIONS FOR ADVANCED DISEASE

CASE 100-4

QUESTION 1: E.S. is a 70-year-old male who is currently receiving leuprolide every 3 months. He was initially diagnosed with metastatic prostate cancer in June 2018 and was found to have four bone metastases at that time. He was initially treated with docetaxel plus prednisone every 3 weeks for six cycles in addition to ADT and now continues with the leuprolide. He comes to the medical oncologist's office for a routine follow-up appointment. His pertinent laboratory results are as follows:

Date	PSA Level (ng/mL)	Testosterone (ng/dL)
July 27, 2018	2.16	
October 20, 2018	2.01	<50
January 10, 2019	2.32	
April 12, 2019	2.27	
July 14, 2019	2.93	
October 26, 2019	3.22	

January 14, 2020	4.57	
April 17, 2020	5.06	<50
July 23, 2020	5.51	
October 10, 2020	8.79	<50

At this follow up appointment, he admits to feelings of fatigue but is otherwise in good health and exercises by walking 3 miles a day. He has no known drug allergies and is only taking lisinopril 10 mg daily for high blood pressure and bupropion HCl extended release (ER) 300 mg daily for depression. The medical oncologist orders a CT scan of the chest, abdomen, and pelvis, the result of which reveals a new mass in the pelvis and liver. His genetic testing shows no abnormalities in *HRR* genes.

What would be the best treatment recommendation for E.S.?

Cytotoxic Chemotherapy

TAXANES

Taxanes are the only class of chemotherapy that has shown a survival benefit in the treatment of metastatic prostate cancer. These agents are microtubule inhibitors, which promote assembly of microtubules and inhibit disassembly, thereby stabilizing microtubules and arresting the cell cycle. Before their development, chemotherapy was generally not effective, with mitoxantrone only providing a relief of symptoms. Currently, taxanes are a standard of care in metastatic prostate cancer, and have a role in both the initial treatment of metastatic, castration-sensitive disease and later in rapidly progressing metastatic CRPC.

Docetaxel

Docetaxel in combination with prednisone is considered the mainstay of therapy for symptomatic, metastatic CRPC when cytotoxic chemotherapy is indicated. Given that there are less toxic therapies available for treatment in this setting, Docetaxel-based regimens were found to improve OS in two randomized phase III

studies. Docetaxel plus prednisone was compared to the previous standard of care, mitoxantrone plus prednisone. When docetaxel-based regimens were given every 3 weeks with prednisone versus mitoxantrone plus prednisone in >1000 males, there was an increase in OS of about 2 months (TAX327: 18.9 vs 16.5 months, *P* = .009 and SWOG9916: 17.5 vs 15.6 months, *P* = .02). Quality of life was similar in both arms of each study.[69,70] Myelosuppression is a dose-limiting toxicity with docetaxel, requiring frequent monitoring for neutropenia and thrombocytopenia. It also carries risks of neuropathy, peripheral edema, and hypersensitivity reactions. Premedication is necessary for the prevention of the latter two toxicities. Docetaxel is extensively metabolized by the liver, with strict criteria to treat before each cycle, because abnormalities of bilirubin and liver functions tests can increase the risk of severe toxicities and death.[71] Tolerability was improved when docetaxel was switched to a lower dose every 2 weeks with less febrile neutropenia and other toxicities.[72] Alternative dosing regimens may be considered in patients unable to tolerate docetaxel on an every 3-week schedule.

Docetaxel is also an option in males with advanced or metastatic, castration-sensitive prostate cancer at the initiation of ADT. The Chemohormonal Therapy Versus Androgen Ablation Randomized Trial for Extensive Disease in Prostate Cancer (CHAARTED) trial illustrated that early initiation of docetaxel plus prednisone every 3 weeks for six cycles in addition to ADT improved survival (57.6 vs 47.22 months, *P* = .002). A subgroup analysis of males with high-volume disease, defined as the presence of visceral metastases or high bone burden, had a median OS of 51.2 versus 34.4 months (*P* < .001); very little benefit was seen in males with lower disease volume. Disease volume should be taken into consideration when deciding the utility of dose intensification with docetaxel therapy at ADT initiation in metastatic castration-sensitive prostate cancer. Adverse effects seen in the combination group included febrile neutropenia and neuropathy.[67,73]

The Systemic Therapy in Advancing or Metastatic Prostate Cancer: Evaluation of Drug Efficacy (STAMPEDE) trial further demonstrated a survival advantage, with the addition of six cycles of

docetaxel at ADT initiation in males with newly diagnosed advanced prostate cancer.[66] In both studies, there was a clinically significant increase in serious toxicities with the use of docetaxel. These studies support the early use of docetaxel chemotherapy with ADT; however, careful patient and treatment consideration must be taken to determine which patients would benefit most with using docetaxel in this setting given the risk of increased toxicity.

Cabazitaxel

Cabazitaxel in combination with prednisone is typically a treatment option after progression on docetaxel-based regimens. In a randomized phase III study of cabazitaxel 25 mg/m^2 every 3 weeks plus prednisone versus mitoxantrone plus prednisone in metastatic patients with CRPC who were docetaxel refractory, there was a 2.4-month improvement in OS (P = .0001), but with more severe adverse effects. Death occurred in 4.9% of patients (vs 1.9% in the mitoxantrone-containing regimen), mostly owing to sepsis and renal failure. Other adverse effects included febrile neutropenia, severe diarrhea, anemia, nausea, vomiting, and fatigue.[74] As with docetaxel, monitoring of complete blood count and liver function is recommended. Cabazitaxel can also cause severe hypersensitivity because of its formulation with polysorbate 80; therefore, premedication is necessary. In an effort to mitigate cabazitaxel toxicities, a phase III trial compared cabazitaxel 20 to 25 mg/m^2 every 3 weeks. The lower dose was found to be noninferior and less toxic, particularly with regard to myelosuppression and febrile neutropenia.[75] Reduced dose of cabazitaxel is now a standard of care in this setting, with the higher dose reserved for fit patients who wish to be more aggressive. There is some evidence to support the use of cabazitaxel before docetaxel in patients with chemotherapy-naive, metastatic CRPC, so it can be considered in patients who are not candidates for docetaxel chemotherapy.[76]

MITOXANTRONE

Before the introduction of docetaxel as first-line cytotoxic chemotherapy, mitoxantrone plus prednisone was considered the only chemotherapy regimen that provided benefit in metastatic CRPC. It did not improve OS, but it did increase the quality of life, as measured by a 29% pain response rate versus 12% with prednisone alone.[77] Because of its lack of benefit in OS and progression-free survival (PFS), it has been relegated to last-line therapy in which there are no other viable therapies for symptomatic relief of advanced metastatic CRPC.

Next-Generation Androgen-Directed Therapy

An increased understanding of the role of androgens in prostate cancer has clarified the concept that the androgen pathway is still active in advanced prostate cancer. This has led to the development of new agents with proven efficacy in advanced prostate cancer that work to inhibit ARs or the enzymes needed for androgen synthesis. Some of the next-generation therapies have demonstrated survival benefit in nonmetastatic CRPC and in metastatic castration-sensitive prostate cancer and in CRPC. As previously mentioned, darolutamide, apalutamide, and enzalutamide have demonstrated a survival benefit in nonmetastatic CRPC. Apalutamide, enzalutamide, and abiraterone have evidence to support their use in metastatic castration-sensitive prostate cancer. Phase III trials have confirmed the utility of abiraterone and enzalutamide in metastatic CRPC both before and after docetaxel. Because of their tolerable toxicity profile and ease of oral administration, abiraterone and enzalutamide can be used before docetaxel in patients who are minimally symptomatic, ineligible and/or unable to tolerate therapy, or in patients preferring less toxic therapy. With the abundant evidence for the use of the next-generation androgen-directed therapies at different points of the disease, treatment selection and sequencing are integral questions when strategizing treatment. There have yet to be any comparative studies to indicate a preference in treatment selection; therefore, both treatment and patient-specific factors must be considered when

selecting the best treatment option. Generally, once a patient progresses on a next-generation androgen-directed therapy, the agent is not considered for reuse.

ABIRATERONE

Abiraterone is an androgen synthesis inhibitor that irreversibly inhibits cytochrome 450 (CYP)17 (17 α-hydroxylase/C17,20-lyase), an enzyme that is required for androgen biosynthesis and is expressed in prostatic, testicular, and adrenal tissue. It inhibits testosterone precursors, dehydroepiandrosterone and androstenedione. When given in combination with prednisone in males with metastatic CRPC who had progressed on docetaxel, a phase III, randomized, placebo-controlled trial found that median OS could be prolonged over 4 months compared to prednisone alone (15.8 vs 11.2 months, $P > .001$).[78,79] There was also a statistically significant improvement in palliation of pain from bone metastases, PSA response rate, and time to PSA progression.[80]

Abiraterone was studied before docetaxel therapy in another randomized phase III trial. Patients with asymptomatic or minimally symptomatic metastatic CRPC had a PFS that was doubled compared to prednisone alone (16.5 vs 8.3 months, $P > .001$). Progression of pain intensity was delayed from 18.4 to 26.7 months.[81] This is a reasonable option in patients before or after docetaxel in patients with metastatic CRPC.

In metastatic castration-sensitive prostate cancer, abiraterone is an approved option for treatment. Two phase III trials of abiraterone with low-dose prednisone demonstrated a survival benefit over ADT alone in this setting. The LATITUDE study evaluated 119 males with high-risk metastatic castration-sensitive prostate cancer. High-risk disease was defined as having at least two of three factors: three or more bone lesions, visceral metastases, or a Gleason score ≥8. In addition to improving OS (53.3 vs 36.5 months), adding abiraterone improved progression, PSA progression, time to subsequent therapies, and other clinical outcomes.[82] The STAMPEDE trial demonstrated a survival advantage with the early use of abiraterone

with ADT in metastatic castration-sensitive cancer in both high-risk and low-risk patients.[83]

Because of the inhibition of abiraterone on CYP17, increased mineralocorticoid production by the adrenals can occur, causing side effects such as hypertension, hypokalemia, and fluid retention. Concomitant use of prednisone reduces the incidence and intensity of these side effects. Abiraterone should be taken orally on an empty stomach (at least 1 hour before or 2 hours after food).[84] A newer micronized, or fine particle, form of abiraterone is also available, used in conjunction with methylprednisolone, and can be taken without regard to food.[85] The most common adverse effects associated with abiraterone include fatigue myalgias/arthralgias, and peripheral edema. Other adverse effects that occurred but were most commonly grade 1 or 2 are diarrhea, constipation, hot flashes, and hypertension. When a patient is started on abiraterone, liver function, potassium, and blood pressure should be monitored closely for the first 90 days and then at least monthly.[84,85]

ENZALUTAMIDE, APALUTAMIDE, AND DAROLUTAMIDE

The newer AR antagonists inhibit the function of the AR by three mechanisms: prevention of binding between androgens and the receptor, prevention of the translocation of AR to the nucleus, and prevention of binding of the AR to DNA.[86,87] Various next-generation AR inhibitors are utilized in both nonmetastatic and metastatic CRPC as well as in metastatic castration-sensitive prostate cancer. These agents are utilized over first-generation antiandrogens in the advanced prostate cancer setting because of their higher affinity for the AR and lack of agonistic properties, as seen with first-generation antiandrogens. In patients with metastatic CRPC, trials have demonstrated efficacy of enzalutamide both before docetaxel therapy (Safety and Efficacy Study of Oral MDV3100 in Chemotherapy-Naive Patients With Progressive Metastatic Prostate Cancer [PREVAIL] trial[88]) and after docetaxel treatment (AFFIRM trial[89]). The results of these two studies demonstrated median OS benefit with enzalutamide over placebo. Quality of life was also

improved in the AFFIRM study. Seizures occurred rarely (<1%), although caution should be used in patients with risk factors for seizure.[90] In patients with nonmetastatic CRPC, median OS was again found (67 vs 56.3 months, *P* = .001) in the Safety and Efficacy Study of Enzalutamide in Patients With Nonmetastatic Castration-Resistant Prostate Cancer (PROSPER) trial.[91]

And in patients with castration-sensitive metastatic prostate cancer, the Enzalutamide in First Line Androgen Deprivation Therapy for Metastatic Prostate Cancer (ENZAMET) trial estimated that the 3-year OS was 80% versus 72% in patients receiving standard of care. All patients received ADT concomitantly.[92] The most commonly reported side effects of enzalutamide include fatigue, back pain, hot flashes, arthralgia, hypertension, and decreased appetite. There is an increased incidence of falls and fractures that require evaluation of patients for these risks.

Apalutamide's approval in nonmetastatic CRPC is based on the Study of Apalutamide (ARN-509) in Men With Non-Metastatic Castration-Resistant Prostate Cancer (SPARTAN) trial of 1207 patients, which demonstrated metastasis-free survival of 40.5 versus 16.3 months with placebo (*P* < .001) if the PSADT ≤10 months and a median OS 73.9 versus 59.9 months with placebo (*P* = .016). Adverse effects included hypertension (25%), rash (25%), diarrhea (20%), nausea (18%), and fatigue (26%–39%).[93] Overall, apalutamide has a side effect profile similar to that of enzalutamide. Apalutamide demonstrated benefit in the phase 3 Study of Apalutamide (JNJ-56021927, ARN-509) Plus Androgen Deprivation Therapy (ADT) Versus ADT in Participants With mHSPC (TITAN) study that included patients with metastatic castration-sensitive prostate cancer. OS at 24 months was 82.4% versus 73.5% in the placebo arm (*P* = .005).[94]

Darolutamide is approved in nonmetastatic CRPC. The phase III Efficacy and Safety Study of Darolutamide (ODM-201) in Men With High-risk Non-metastatic Castration-resistant Prostate Cancer (ARAMIS) study in patients with a PSADT ≤10 months demonstrated a metastasis-free survival of 40.4 versus 18.4 months with placebo (*P* <.001), with a final analysis of a 31% decrease in risk of death

with darolutamide. The most common adverse effects were <15% and included fatigue, pain in an extremity, and rash.[95,96] Darolutamide is not associated with an increased incidence of seizures, falls, or fractures as it is with the other second-generation AR inhibitors. It is thought that darolutamide's lower incidence of seizure and other central nervous system–related adverse effects may be attributed to its low blood–brain barrier penetration.[96] In addition, darolutamide has less drug interaction potential given that it is not a potent inducer of CYP enzymes as are enzalutamide and apalutamide.[97]

Other Secondary Hormone Manipulation

There are other possible secondary hormone manipulations that can be used for treatment in nonmetastatic CRPC and in metastatic prostate cancer such as antiandrogens, antiandrogen withdrawal, ketoconazole, glucocorticoids, and estrogens. However, they are now rarely used in practice given that they are not as potent as the newer antiandrogens and have not shown a survival benefit. It is possible to use these agents sequentially after alternative treatments with proven survival benefit have been exhausted.

The addition of a first-generation antiandrogen for CAB is a possible treatment option for patients with CRPC (see Table 100-3). Because of the multiple daily dosing of flutamide and the additional side effect of delayed dark vision adaptation of nilutamide, bicalutamide is typically the preferred agent. Although these agents are generally well tolerated, adverse effects can include hepatic toxicities requiring monitoring for elevations in liver enzymes. Pulmonary-associated side effects are rare, but serious toxicity is possible with these agents.[4]

For a patient already on a first-generation antiandrogen, discontinuation of the agent after progression on CAB can result in a decline in PSA level, called *antiandrogen withdrawal syndrome*. This response can be seen in ~20% of patients and can be attempted before initiation of another treatment.[98]

Ketoconazole is an antifungal agent that is an inhibitor of adrenal androgen synthesis. The testes produce nearly 90% of testosterone in males, with the remaining 10% derived from the androgens produced in the adrenal glands. The androgens are subsequently converted to testosterone and DHT. For prostate cancer treatment, ketoconazole must be administered three times daily under low gastric pH conditions along with a glucocorticoid. Its complex administration in addition to frequent gastrointestinal toxicities and high potential for drug interactions limit its use. It should not be used if the patient has already progressed on abiraterone because they are both CYP17A1 inhibitors.[4]

Several different glucocorticoids and estrogens have historically been utilized in the treatment of prostate cancer. It is still unknown exactly how these agents act in CRPC. It is thought that estrogen can cause suppression of LH release from the pituitary to then reduce testosterone production in the testes. Glucocorticoids, such as hydrocortisone, dexamethasone, and prednisone, may suppress adrenal androgen synthesis by reducing the production of adrenocorticotropic hormone (ACTH) in the pituitary. These agents have somewhat fallen out of favor given their toxicities and the increased number of options that are now available.[4]

Immunotherapy

SIPULEUCEL-T

Sipuleucel-T is the first cancer vaccine to be approved by the U.S. Food and Drug Administration (FDA). Unlike vaccines that prevent infection by allowing the immune system to recognize the virus or bacteria, a cancer vaccine treats the cancer. This cancer vaccine stimulates a patient's own immune system against the prostatic acid phosphatase (PAP) antigen that is expressed in most prostate cancer tissues. Collection of a white blood cell fraction containing antigen-presenting cells is taken from the patient and then exposed to prostatic acid phosphatase-granulocyte macrophage colony-stimulating factor (PAP–GM–CSF recombinant fusion protein). The

activated cells are then reinfused into the patient 3 days after collection. The infusion is repeated every 2 weeks for a total of three treatments. The randomized, double-blind, placebo-controlled phase III study was conducted in >500 males with minimally symptomatic or asymptomatic metastatic CRPC without visceral metastases. Median OS was 25.8 versus 21.7 months in the placebo group (*P* = .03). Treatment was well tolerated, with common adverse effects of chills (54.1%), pyrexia (29.3%), and headache (16%). Close monitoring of cardiac and pulmonary conditions during infusion and premedication with an antihistamine and acetaminophen is recommended to alleviate the commonly reported acute infusion reactions, which can include chills, fever, respiratory events, hypertension/hypotension, tachycardia, syncope, nausea, vomiting, and fatigue. These reactions are typically mild to moderate in nature and can subside within 1 to 2 days of infusion. If acute infusion reaction is more severe, the infusion rate can be reduced.[99] Unlike other treatments for metastatic CRPC, sipuleucel-T does not elicit a change in PSA level that can be used as an objective measure of response. This is a treatment option for metastatic patients with CRPC who are slowly progressing, with little or no symptoms, for which immediate response to treatment is not required. Because sipuleucel-T has not been studied in patients with visceral metastases, it is typically not recommended in these patients.[99]

PEMBROLIZUMAB

If tumor testing identifies an advanced prostate cancer as having a large number of mutations, then it may be categorized as having high levels of microsatellite instability (MSI-H) or deficient mismatch repair (dMMR). Those patients may be eligible for pembrolizumab immunotherapy. Pembrolizumab is a monoclonal antibody that binds to the programmed cell death 1 (PD-1) receptor on T cells and blocks its interaction with its ligand (PDL-1 and PDL-2) to help restore the activation of T-cell–mediated immune response against tumor growth. The use of pembrolizumab in solid tumors is approved in patients with unresectable or metastatic MSI-H/ dMMR cancer

who have progressed on prior treatment or who have no satisfactory alternative treatment options. It is given at a flat dose of 200 mg every 3 weeks. Common side effects can include fatigue, decreased appetite, pruritus, diarrhea, nausea, rash, pyrexia, cough, and dyspnea. Less common, but severe and potentially fatal immune-mediated adverse reactions are possible in any organ system, including pneumonitis, colitis, hepatitis, endocrinopathies, nephritis, and dermatologic reactions. Close and frequent monitoring for signs and symptoms and immediate management often using corticosteroids is necessary for these immune-mediated adverse effects.[100]

Poly-ADP Ribose Polymerase Inhibitors

Defects in DNA damage repair pathway occur in a significant proportion of advanced prostate cancers. Genetic testing can reveal mutations in *HRR* genes, which can include *BRCA1/2*, *CHEK1/2*, *ATM*, *PALB2*, *FANCA*, and *RAD51*, among others.[101] These genes are involved in the repair of DNA double-strand breaks. PARP function includes repairing single-strand breakthrough base excision repair. PARP inhibitors trap PARP on DNA and prevent the repair of the single-strand breaks. The deficiencies in DNA repair caused by either an *HHR* gene mutation or by PARP inhibitors may not individually cause cytotoxicity, but the combined effect of overwhelming accumulation of DNA damage will ultimately cause cell death, a concept known as *synthetic lethality*.[101,102] There is growing evidence supporting the efficacy of PARP inhibitors in patients with prostate cancer having HRR deficiencies. Currently, two agents, olaparib and rucaparib, are approved in this setting.

A phase III trial of males with metastatic CRPC who progressed on a next-generation androgen-directed therapy and up to one taxane (permitted but not required) were randomized to olaparib 300 mg twice daily versus physician's choice. All patients had to have *HRR* mutation. The primary end point of radiographic PFS was significantly increased in the HRR cohort, and OS was also improved

in patients specifically with *BRCA 1/2* or *ATM* mutations.[103] Not all patients received prior docetaxel in this study; therefore, olaparib may be a treatment choice for patients with metastatic castration-resistant prostate cancer (mCRPC) having *HRR* mutations that have been treated with an androgen-directed therapy either before or after docetaxel treatment.

Rucaparib was evaluated in a phase II trial of patients with mCRPC having *HRR* mutations that progressed on prior androgen-directed therapy and prior taxane therapy. The trial demonstrated an objective response rate (ORR) of 44% in patients with *BRCA 1/2* mutation leading to its approval in this setting.[104]

PARP inhibitors are relatively well tolerated, with the most significant toxicities being hematologic and gastrointestinal. Monitoring of complete blood counts is recommended given the risks of anemia, thrombocytopenia, and neutropenia, and dose interruptions and reduction may be necessary for counts to recover. Antiemetics should be offered to patients to prevent nausea and vomiting. A small, but potentially fatal, risk of myelodysplastic syndromes can occur with the use of PARP inhibitors. Further research is being conducted on these agents, as well as other PARP inhibitors, to better define their role in the treatment of patients with advanced prostate cancer having *HRR* mutations.[105,106]

Radium-223

In patients with CRPC and symptomatic bone metastases and no known visceral metastases, radium-223 dichloride has been shown to increase median OS (14.9 months with radium-223 vs 11.3 months with placebo) and to reduce pain when given every 4 weeks for six cycles. It also delayed time to first skeletal event (15.6 vs 9.8 months, $P > .001$). It emits high-energy alpha particles that target bone metastases by binding to areas of increased bone turnover. The short-range radiation creates a localized toxic effect of double-stranded DNA breaks in these targeted areas. Adverse effects were consistently similar between the active and placebo arms, although

there was a slightly higher rate of myelosuppression with radium-223. More participants in the placebo arm discontinued the study drug because of adverse events.[107] Radium-223 should not be used in combination with docetaxel or other systemic therapies for prostate cancer treatment. It can be used in conjunction with ADT with the exception of abiraterone and prednisone, in which a higher risk of fracture has been suggested.[108]

E.S. has a rising PSA despite castrate levels of testosterone. He has CRPC with metastases to the bone and liver, which makes him ineligible for sipuleucel-T and radium-223. He could potentially receive chemotherapy; however, he is not rapidly progressing and is not significantly symptomatic. A next-generation androgen-directed therapy would be most appropriate. Abiraterone or enzalutamide are treatment choices for E.S. Given that he is on bupropion, which can lower seizure threshold, abiraterone may be the most appropriate choice, given the risk of seizure with enzalutamide, and medications that lower seizure threshold can increase that risk.

Bone Metastases

Case 100-4, Question 2: E.S. is tolerating treatment with abiraterone well. Because E.S. now has CRPC with high-volume bone metastases, what recommendations can be made to decrease the risk of skeletal-related events?

Bone metastases occur in around 90% of males who develop metastatic prostate cancer and are a common complication in advanced disease.[109] Prostate cancer bone metastases are primarily osteoblastic lesions, in which there is increased bone formation around tumor deposits. In addition, there is increased osteoblastic bone resorption or osteolysis.[4] They may be asymptomatic, but can frequently cause pain, decreased mobility, and diminished quality of life. These metastases can also cause skeletal-related events, which include pathologic fractures, need for radiation or surgery to the bone, and spinal cord compression. There are several systemic therapies for the treatments of advanced prostate cancer, such as

abiraterone, enzalutamide, docetaxel, and radium-223 that have shown not only an improved survival but also a delay in bone-related complications or improvement in bone-related pain. Several of the following treatments are specifically used to prevent skeletal-related events and/or improve symptoms from bone metastases in patients with prostate cancer.[69,80,107,110]

BISPHOSPHONATES

The only bisphosphonate shown to be of benefit in patients with CRPC and bone metastases is zoledronic acid. It was shown to decrease the frequency of skeletal-related events compared to placebo. There was also a prolonged time to first skeletal-related event and decrease in pain and analgesic score in patients treated with zoledronic acid.[111] It is approved at a dose of 4 mg intravenously every 3 to 4 weeks but must be dose reduced in renal dysfunction, and it is not recommended to use if renal clearance is <30 mL/minute. Zoledronic acid does not provide benefit in patients with castrate-sensitive prostate cancer, so it should only be used in patients with CRPC with bone metastases. Patients should take calcium and vitamin D as necessary to prevent hypocalcemia. An uncommon but serious adverse effect of osteonecrosis of the jaw can occur with zoledronic acid use.[4] Patients should be advised on the importance of good oral hygiene, a baseline dental evaluation, and avoiding invasive dental procedures during therapy, if possible, to minimize their risk.[108,112]

RECEPTOR ACTIVATOR OF NUCLEAR FACTOR-KB LIGAND INHIBITORS

Denosumab is a monoclonal antibody for the receptor activator of nuclear factor-kB ligand (RANKL), which is involved in osteoclast-mediated bone resorption and remodeling.[108] When compared to zoledronic acid in metastatic CRPC, denosumab was more effective at preventing the skeletal-related events of pathologic fractures, need for radiation or surgery to bone metastases, or spinal cord compression. Denosumab also restored bone density.[4] The serious

adverse effect of concern associated with denosumab is the same as that with bisphosphonates, osteonecrosis of the jaw, and it has a higher rate of hypocalcemia. Renal adjustment is not necessary for denosumab dosing; however, renal function should be monitored, particularly because of the increased risk of hypocalcemia and hypophosphatemia in patients with renal clearance <30 mL/minute. For bone metastases occurring in patients with CRPC, denosumab is given as 120 mg subcutaneously every 4 weeks. Patients should take calcium and vitamin D to prevent hypocalcemia.[108,113]

SYSTEMIC RADIOTHERAPY

Systemic radiotherapy may be used with radium-223, delaying time to first skeletal event in symptomatic bone metastases, as discussed previously. It is the only bone-targeting agent with a survival benefit and can be a good choice for patients with extensive bone disease with otherwise minimal disease.[108] Two β-emitting radiotherapy agents that have been utilized are strontium-89 or samarium-153 in patients with painful bone metastases that are not responsive to palliative chemotherapy and pain medications. However, they have no survival benefit, and myelosuppression is a major concern that must be factored into the future plan if additional chemotherapy is to be used.[114]

EBRT, although not systemic radiotherapy, is an option for one or a few symptomatic sites of bone metastases. It is most often used to provide symptomatic relief.

E.S. should start taking calcium and vitamin D supplementation and can add weight-bearing exercises to his daily walking. In addition, his medical oncologist can recommend either zoledronic acid every 3 to 4 weeks or denosumab every 4 weeks.

ADVERSE EFFECTS OF PROSTATE CANCER THERAPY

Because of the large number of males who are diagnosed with prostate cancer, as well as the continuously increasing numbers of those who live a considerable amount of time after therapy, the adverse effects of cancer therapy should remain a consideration for the remainder of the patient's life. It should be recognized that these effects include both short- and long-term issues. Patients should be aware of these potential adverse effects and their management strategies in a discussion with their physician. Guidelines from the American Cancer Society are available for the primary care physician regarding long-term survivorship of patients with a prior diagnosis of prostate cancer.[115]

Androgen Deprivation Therapy

The loss of the majority of testosterone with the use of ADT in a male can cause a variety of symptoms that can negatively impact the quality of life. The large number of males living after a diagnosis of cancer should be aware of the long-term adverse effects of this therapy. The American Society of Clinical Oncologists (ASCO) survivorship guidelines recognize these problems and give recommendations for their monitoring. These include health promotion, screening for secondary cancers, rectal and urinary symptoms, cardiovascular and metabolic effects, anemia, bone health, sexual dysfunction, and vasomotor symptoms.[115]

VASOMOTOR SYMPTOMS

CASE 100-5

QUESTION 1: P.L. is a 63-year-old male who has been on ADT therapy for just over a year, and is experiencing hot flashes and mild depression. He also had a bone mineral density scan, indicating ADT-induced osteopenia.

What can P.L.'s medical oncologist offer him to alleviate some of the side effects and complications he is experiencing from ADT treatment?

Vasomotor symptoms will bother many males for the duration of their treatment with ADT, with an incidence of up to 40%. Hot flashes are characterized by an intense heat sensation, flushing, and diaphoresis, involving the face and trunk and may also include anxiety and palpitations. These effects can vary in frequency, intensity, and duration. The mechanism may be because of a withdrawal of androgens, disrupting the equilibrium of the norepinephrine and serotonin neurotransmitters. Data have been taken from females as well as from males in the efficacy of these agents because most therapies have seen similar efficacy in both males and females. These agents include, among others, selective serotonin reuptake inhibitors, serotonin–norepinephrine reuptake inhibitors, and gabapentin.[115,116]

Gabapentin has been one of the most studied drugs for the treatment of hot flashes in males. Gabapentin at doses of up to 900 mg/day in males on ADT showed a significant reduction in hot flashes.[117] Titration recommendations are to start at 300 mg daily and increase in increments of 300 mg to achieve the final dose. Pregabalin, which has shown some benefit in females at doses of 150 to 300 mg/day, has not been studied in males but may be a reasonable option starting at doses of 75 mg twice daily.

Serotonin and serotonin–norepinephrine reuptake inhibitors have also shown benefit in males on ADT, although no placebo-controlled, randomized trials have been done to date. Venlafaxine has been the most extensively studied from this drug class at varying doses. Paroxetine has also been studied in males on ADT. The use of other agents in these classes has also been reported.[115,118]

Alternative therapies have also been used to treat hot flashes. Acupuncture has shown some promise in small studies. Soy and herbal products have also been used; however, randomized controlled studies must be done to determine the true benefit of these therapies.[116]

CARDIOVASCULAR AND METABOLIC ADVERSE EFFECTS

There is a concern of an association between ADT and risk of mortality from cardiovascular disease. Although this has not been seen consistently in clinical trials, congestive heart failure and myocardial infarction have been identified as a risk highest in those who already have a risk of cardiovascular disease. A meta-analysis of studies with nonmetastatic and non-CRPC did not find a significant difference in cardiovascular death in those males treated with ADT versus those who were not. The American Heart Association advisory panel concluded that links remain controversial, and do not recommend periodic cardiac testing, but screening for cardiovascular risk factors should occur and monitoring of blood pressure, lipid profiles, and serum glucose should be routine, especially in those males who receive >6 months of ADT.[119] Males with a recent history of cardiovascular disease may be at higher risk.[115,120]

Androgen deprivation has been shown to increase the risk of obesity, decrease lean muscle mass, decrease insulin sensitivity, increase high-density lipoprotein levels, and increase subcutaneous fat accumulation. Screening for diabetes and hypercholesterolemia is necessary, particularly with long-term use of ADT.[4,115]

SEXUAL ADVERSE EFFECTS

Loss of libido and erectile dysfunction are expected adverse effects of ADT, occurring in up to 85% of males treated with ADT. The impact of ADT therapy may be delayed, with full effect occurring up to 2 years later.[115,121] Recovery from erectile dysfunction will usually occur after cessation of therapy. However, for patients on long-term therapy, there should be an open dialog between the health care team and the patient regarding options available to help in mitigating these effects.[115] Other factors that may be contributing to erectile dysfunction should also be considered, including a history of diabetes or cardiovascular disease as well as whether the patient has had a previous prostatectomy or radiation to the prostate. There is no consensus regarding the best therapy for this adverse effect.

Phosphodiesterase inhibitors can be offered because 44% of patients reported a benefit in one study.[115,121,122]

PSYCHOLOGICAL/COGNITIVE ADVERSE EFFECTS

Psychosocial adverse effects such as distress, depression, and cognitive impairment may occur. It has been estimated that up to 30% experience distress, 25% have increased anxiety, and almost 10% have a major depressive disorder. Low testosterone levels can affect mood in some males, causing depression and short temper. Routine assessment is crucial to identifying those patients experiencing these effects that can have a major impact on survivorship and quality of life with referral for behavioral intervention considered, as necessary.[115,123,124]

BONE HEALTH ADVERSE EFFECTS

Patients treated with ADT are more susceptible to decreased bone mineral density and bone fractures. In a study looking retrospectively at males diagnosed with prostate cancer from 1992 to 1997, those who received ADT therapy were compared to those who did not and were found to have a higher incidence of fractures (19.4% vs 12.6%, $P > .001$). ADT increases bone turnover and decreases bone mineral density with a 21% to 54% relative increase in fracture risk. Rapid loss of bone mineral density is seen within 6 to 12 months.[125]

The Prostate Cancer Survival Guidelines of the ASCO suggest that all males who have received ADT should be assessed for the risk of fracture, using a baseline dual-energy x-ray absorptiometry (DEXA) scan and calculation of a FRAX® (Fracture Risk Assessment Tool) score.[115] For those males who are determined as being high risk, there are a number of options. Alendronate 70 mg weekly, zoledronic acid 5 mg annually, or denosumab 60 mg every 6 months are available for use in this setting.[6,108] Patients are recommended to take calcium and vitamin D supplementation according to age-appropriate guidelines and possibly more in patients who are deficient.

P.L.'s medical oncologist can offer P.L. an antidepressant. Gabapentin, venlafaxine, and acupuncture have been shown to have some benefits for vasomotor symptoms, such as hot flashes. If P.L. is interested in being treated for both his depression and hot flashes, venlafaxine may be a good option because it can treat both side effects at the appropriate dose. As for P.L.'s osteopenia, weight-bearing exercises, supplementation of vitamin D and calcium, and the addition of yearly zoledronic acid or biyearly denosumab can be given to prevent complications that can arise from bone loss.

Radiation Effects

CASE 100-6

Question 1: C.W. has been recently diagnosed with unfavorable intermediate-risk prostate cancer. He discusses his options for definitive local treatment with the medical oncologist, radiation oncologist, and urologist. He decides to undergo radiation, and the radiation oncologist plans to treat him with EBRT in conjunction with 6 months of ADT.

What side effects from treatment can C.W. expect? What concerns will the medical oncologist have regarding side effects and his history (PMH, FH, and SH)?

SEXUAL SIDE EFFECTS

Erectile dysfunction is the most commonly seen sexual adverse effect of radiation but can include decreased volume of ejaculate, absence of ejaculate, decreased intensity of orgasm, and decreased libido. Erectile dysfunction ≥3 years after EBRT occurs in 36% to 68% of patients and 50% to 60% of males have some extent of erectile dysfunction with brachytherapy. With radical prostatectomy, erectile dysfunction is seen soon after surgery but may improve over time. This is the opposite of what is seen with radiation, where it is more of a slow decline.[6,115]

In one study, 80% of patients receiving radiation therapy responded well to sildenafil. It was seen that 74% of patients in another study continued to respond after 4 years. Additional factors

that may contribute to erectile dysfunction should be considered, such as coronary artery disease and diabetes as well as patient age. Some patients will not respond and should be referred to a urologist or sexual health expert to evaluate other options for treatment.[121,122]

EXTERNAL BEAM RADIATION THERAPY

Radiation treatment for definitive local treatment is typically 4 to 6 weeks long, with acute symptoms usually occurring around the third week and resolving within days to weeks of completion of treatment. Symptoms such as diarrhea can be treated with standard agents (eg, loperamide, diphenoxylate/atropine). Internal or external hemorrhoids can become inflamed, and sitz baths and hydrocortisone suppositories can help alleviate symptoms. Also, acute urinary symptoms may occur with agents such as phenazopyridine and α-blockers such as tamsulosin providing benefit.[4,6,115]

Late rectal toxicities from radiation therapy can occur 12 to 18 months after completion of EBRT and persist for several years, although developing adverse effects after 5 years is rare. These adverse effects can include rectal bleeding, mucous discharge, and mild incontinence of stool. Rectal bleeding can be controlled with increased fiber in the diet, steroid suppositories, and sitz baths, with rectal ulcers and fistulas occurring in <1% of patients.[4,6,115]

Late urinary toxicities consist of chronic urethritis in 10% to 15% of patients and urethral strictures in 2% to 3%.[4,6,115]

BRACHYTHERAPY

Brachytherapy allows for the radiation of small areas of the prostate, which decreases some of the adverse effects of EBRT. In low-dose brachytherapy, acute urinary retention is known to occur in 6% to 15%, although better identification of risk factors for its development has decreased the incidence to ~6% in recent years. Transient urinary effects that occur include radiation-induced urethritis or prostatitis, urinary frequency, urgency, and dysuria. Symptoms will peak about 1 to 3 months after brachytherapy is placed and

gradually resolve over the subsequent couple of months. α-Blockers such as tamsulosin help relieve some of these symptoms.[4,115]

C.W. may experience some of the common symptoms from EBRT, which include diarrhea and hemorrhoids. Other urinary and rectal symptoms include rectal urgency and increased urinary and bowel frequency; and erectile dysfunction may also occur. ADT can cause many side effects, as listed in **Table 100-4**. The most common adverse effects include loss of libido, erectile dysfunction, hot flashes, weight gain, and muscle loss. Because C.W. already has hypercholesterolemia and suffers from depression, which can be impacted by the use of ADT, C.W.'s medical oncologist must closely monitor for changes in these comorbidities and be proactive about treating them if needed.

Table 100-4

Adverse Effects of Androgen Deprivation, Approximate Frequency, and Potential Therapeutic Options for Amelioration

Effect	Approximate Frequency	Potential Corrective Actions
Libido loss	Universal	None known
Erectile dysfunction	Universal	None known
Hot flashes	50%–80%	Venlafaxine, estrogens, progestins
Muscle loss	Common, duration dependent	Exercise
Weight gain	Common	Exercise/diet
Facial/body hair loss	Very common	None known
Fatigue	Not defined	Exercise
Emotional liability	Not defined	None known
Depression	0%–30%	Various antidepressants
Cognitive dysfunction	Not defined	None known
Gynecomastia	Up to 20%	Preemptive radiation
Breast tenderness	Not defined	Aromatase inhibitors

Effect	Approximate Frequency	Potential Corrective Actions
Osteoporosis	Common, duration dependent	Exercise/bisphosphonates
Anemia	5%–13%	Erythropoietin not recommended
Hyperlipidemia	10%	Diet, statins
Diabetes	0.8%/year increase	Exercise, oral agents
Myocardial infarction	0.25%/year increase	Treatment of risk factors
Coronary heart disease	1%/year increase	Treatment of risk factors

A number of events are poorly defined in frequency as a consequence of a lack of controlled studies, quantitative assessments, and/or agreed on definitions.

PREVENTION

CASE 100-7

QUESTION 1: A.G. is a 42-year-old, African American male who has come to his doctor's office to discuss potential ways to decrease his risk of prostate cancer. His father was diagnosed with prostate cancer at age 49 years, and his brother has just been diagnosed at age 45 years.

What should A.G.'s physician discuss with him about the use of 5-α-reductase inhibitors?

Because of the large number of males who develop prostate cancer, interest has turned to the possibility of prevention. There has been particular interest in the potential of drugs or supplements to at least lower the risk or possibly prevent the occurrence of prostate cancer.

The largest trials to date have involved the 5-α-reductase inhibitors, finasteride and dutasteride. Finasteride is a competitive

inhibitor of type II 5-α-reductase that blocks the conversion of testosterone to DHT in prostatic cells. In the PCPT, >18,000 males ages 55 or older were included if they had a baseline PSA of ≤3 and a normal DRE. They were randomized to finasteride 5 mg daily or placebo and had annual DREs and PSA measurements. At the 7-year follow-up, a 24.8% reduction in the prevalence of prostate cancer was seen for those males on finasteride. There were more reports of sexual side effects, but were less likely to have lower urinary tract symptoms, which can be attributed to finasteride's mechanism of action and its use in BPH. However, for those males on finasteride, there was a larger proportion of cancers considered to be higher grade. The 10-year survival rates showed no significant difference between finasteride and placebo. Updated data at 15 years found that fewer prostate cancers had been diagnosed in the finasteride arm (10.5% vs 14.9%, $P > .001$) and that the survival was similar between the finasteride and placebo arms (78% and 78.2%; HR 1.02, 95% CI 0.97–1.08, $P = .46$). The difference in the risk of death was not significant between the two groups. Overall, finasteride reduced the risk of prostate cancer by about one-third, with a 25% lower risk of death from prostate cancer, but because of the low number of deaths, the difference was not statistically significant.[126]

Dutasteride, a type I and II 5-α-reductase inhibitor, was studied in a 4-year randomized, double-blind, placebo-controlled trial in which males were given either dutasteride 0.5 mg daily or placebo. These males were between ages 50 and 75 years with a PSA between 2.5 and 10 ng/mL and one negative prostate biopsy within 6 months. There was a relative risk reduction of 22.8% over the 4-year period ($P > .001$). The difference between those with a high-grade tumor was not significant between the two groups. Erectile dysfunction and decreased libido were more common in the dutasteride group, although the symptoms of BPH were less in the dutasteride group. Less than 5% of males discontinued the study drug because of drug-related adverse events.[127]

The Selenium and Vitamin E Cancer Prevention Trial (SELECT) trial assessed the use of selenium and vitamin E in the prevention of

prostate cancer. Research has indicated that reactive oxygen species may be associated with the onset and progression of various malignancies, including prostate cancer. This was a phase III, randomized, double-blind, placebo-controlled trial to assess the efficacy of selenium 200 µg daily and vitamin E 400 international units (IU) daily, either alone or in combination. More than 35,000 males who had a normal DRE and a PSA level >4 ng/mL were included in this study. At a median of 5.46 years, no difference was seen among the groups.[128]

A.G.'s physician should explain that the 5-α-reductase inhibitors did show a significant decrease in the incidence of prostate cancer, but that it is still not clear what impact they have on prostate cancer survival. In addition, there are side effects that patients may experience with these medications, such as erectile dysfunction and decreased libido.

SURVIVORSHIP

Because of the large numbers of prostate cancer diagnoses and the generally slow growth of the tumor, there are a large number of males who are living with or after a diagnosis of prostate cancer. They account for about 20% of all cancer survivors. It is recognized that physical and psychosocial effects can occur long after treatment is complete. The American Cancer Society created guidelines, last updated in 2014 and endorsed by ASCO in 2015, for the primary care physician to monitor the health of prostate cancer survivors.[115]

Quality of life should be assessed at baseline and monitored at least annually using one of the validated surveys for this purpose, the 5-item Sexual Health Inventory for Men or the International Index of Erectile Function. These are beneficial for identifying side effect burden or other adverse effects that are of concern to the patient.[115]

Healthy Lifestyle

Guidelines include an emphasis on reminding patients of the benefit of achieving and maintaining a healthy weight, getting enough physical exercise, and eating a diet that is high in fruits, vegetables, and whole grains. For those patients with residual bowel problems that impact absorption, they should be referred to a registered dietitian. The guidelines also include cautions on avoiding alcohol or limiting it to no more than two drinks a day, as well as tobacco use and offering cessation counseling if necessary. Smoking increases the chance of recurrence as well as that of second cancers.

Obesity is associated with increased prostate cancer–specific mortality and biochemical recurrence. Body mass index and healthy food choices along with physical activity should be addressed and encouraged by the primary care physician.

Physical activity has been shown to improve cancer-specific survival and OS, help speed up recovery from short-term effects of therapy, and prevent some long-term effects. Exercise can improve fatigue, anxiety, depressive symptoms, self-esteem, happiness, and quality of life. Patients should be encouraged to engage in at least 150 minutes of physical activity per week.[115]

Surveillance

Once treatment is complete, the PSA should be monitored every 6 to 12 months for the first 5 years and then annually. An annual DRE is also appropriate, especially because some patients will not have a PSA elevation in the setting of cancer. Also, those patients who have received pelvic radiation are at an increased risk for bladder and colorectal cancers. They should have routine screening, and any signs of hematuria and rectal bleeding or pain should be referred back to their treating radiation oncologist for evaluation.[6,115]

101

Hematopoietic Stem Cell Transplantation

Valerie Relias

CORE PRINCIPLES		CHAPTER CASES
1	Hematopoietic stem cell transplantation (HSCT) is a life-saving medical procedure involving the infusion of hematopoietic stem cells into a patient, the HSCT recipient, to treat malignant and nonmalignant diseases and/or restore normal hematopoiesis and lymphopoiesis.	**Case 101-1 (Question 1) Case 101-2 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
2	In autologous HSCT, the donor and recipient are the same individual, eliminating the need for pretransplantation and posttransplantation immunosuppression. Autologous hematopoietic cells must be obtained (ie, harvested) before the myeloablative preparative regimen is administered and subsequently stored for administration after the preparative regimen.	**Case 101-1 (Questions 2, 3)**
3	Posttransplantation pharmacotherapy for autologous HSCT includes hematopoietic growth factors to stimulate the proliferation of committed progenitor cells and to accelerate hematopoietic recovery.	**Case 101-1 (Question 6) Case 101-2 (Question 8)**
4	Common complications after autologous HSCT are infections and organ failure, which occur in <5% of patients. The most common cause of death after autologous HSCT is recurrence of the primary disease.	**Case 101-1 (Question 5)**

CORE PRINCIPLES		CHAPTER CASES
5	Allogeneic HSCT involves the transplantation of hematopoietic stem cells obtained from a donor's bone marrow, peripheral blood progenitor cells (PBPCs), or umbilical cord blood to a patient. The donor for an allogeneic HSCT may be an unrelated or related individual. Histocompatibility determination between donors and recipients must be performed through human leukocyte antigen (HLA) typing. The preparative regimen is, in part, determined by the degree of mismatch between the donor and the recipient.	**Case 101-2 (Questions 2, 3)**
6	The function of the preparative regimens for autologous HSCT is to eradicate residual malignancy. The function of the preparative regimen in allogeneic HSCT is to not only eradicate the residual malignancy but also to provide immunosuppression, allowing the transplanted stem cells to grow and create a graft-versus-tumor effect.	**Case 101-1 (Question 4) Case 101-2 (Question 4)**
7	Choice of preparative regimens for HSCT depends on factors such as underlying disease, degree of HLA matching, stem cell source, patient age, and comorbid conditions. Preparative regimens differ in intensity and are distinguished as myeloablative or nonmyeloablative.	**Case 101-2 (Questions 5, 6)**

CORE PRINCIPLES		CHAPTER CASES
8	Posttransplantation immunosuppressive therapy is necessary for allogeneic HSCT to prevent both graft rejection and acute and/or chronic graft-versus-host disease (aGVHD/cGVHD). Some immunosuppressants require therapeutic drug monitoring to ensure effectiveness while minimizing toxicity.	**Case 101-2 (Question 7) Case 101-4 (Question 1) Case 101-5 (Questions 1–9)**
9	Posttransplantation complications of myeloablative preparation regimens such as hemorrhagic cystitis, mucositis, and sinusoidal obstructive syndrome (SOS)/veno-occlusive disease (VOD) require pharmaceutical management.	**Case 101-2 (Questions 8, 9) Case 101-3 (Questions 1–9)**
10	Opportunistic infections are a major cause of morbidity and mortality after myeloablative and nonmyeloablative HSCT. The primary pathogens vary based on the time posttransplant and include bacterial, fungal, and viral species.	**Case 101-6 (Questions 1–3) Case 101-7 (Questions 1–3)**
11	Long-term complications of HSCT include cGVHD, endocrine dysfunction, and secondary cancers.	**Case 101-5 (Questions 7–9) Case 101-8 (Question 1)**

INTRODUCTION

Worldwide, more than 32,000 autologous and 25,000 allogeneic hematopoietic stem cell transplantations (HSCTs) are performed

annually.[1] The rationale behind the use of hematopoietic stem cells (HSCs) is based on the steep dose response of chemotherapy; however, with increasing doses of chemotherapy, bone marrow (BM) suppression becomes a dose-limiting side effect. The administration of HSCT provides recovery of the BM.

HSCT is a procedure that involves the infusion of hematopoietic stems cells into patients who have received high doses of chemotherapy and/or radiation. Variations of this procedure depend on the donor of these stem cells, self versus nonself, and the source of the stem cells. Autologous stem cell transplants are ones in which the patient serves as the donor of HSCs, whereas, in allogeneic transplants, the donor is another related individual such as a sibling, or an unrelated donor. The source of the HSCs may be from peripheral blood progenitor cells (PBPCs), BM, or umbilical cord blood.

The type of HSCT performed depends on a number of factors, including type and status of the disease, patient age, performance status, and organ function, and, if allogeneic transplant is needed, the availability of a compatible donor. Characteristics of autologous and allogeneic transplantation, with either myeloablative or nonmyeloablative preparative regimens, are compared in **Table 101-1**.[2] Many diseases are treated with autologous or allogeneic HSCT and are listed in **Table 101-2**.[2] Modifications to the basic schema for HSCT are necessary based on the immunologic source (ie, allogeneic or autologous) and the anatomic source (ie, BM, PBPCs, or umbilical cord blood) of the HSCs infused.

Table 101-1
Comparison of Types of Hematopoietic Stem Cell Transplants

Risk[a]	Myeloablative		Nonmyeloablative
	Autologous	Allogeneic	Allogeneic
Relapse after HSCT	+++	+	+
Rejection	–	+	++
Delayed engraftment	++	+	+
GVHD	–	+	++
Infection	+	++ to +++[b]	++ to +++[b]
Transplant-related morbidity	+	+++	++
Transplant-related mortality	+	++	+
Cost of procedure	++	+++	++ to +++

GVHD, graft-versus-host disease; HSCT, hematopoietic stem cell transplant.

[a]Risk varies depending on underlying disease, patient characteristics, and previous medical history.

[b]Risk of infection increases with intensity and duration of immunosuppression and/or chronic GVHD.

Table 101-2
Diseases Commonly Treated with Hematopoietic Stem Cell Transplantation

Allogeneic
Nonmalignant
Aplastic anemia
Thalassemia major
Severe combined immunodeficiency disease
Wiskott–Aldrich syndrome
Fanconi anemia
Inborn errors of metabolism
Malignant
AML
Acute lymphoblastic leukemia
Chronic myeloid leukemia
Myelodysplastic syndrome
Myeloproliferative disorders

Allogeneic
NHL
Hodgkin disease
Chronic lymphocytic leukemia
Multiple myeloma
Juvenile myelomonocytic leukemia
Autologous
Malignant
NHL
Multiple myeloma
AML
Hodgkin disease
Neuroblastoma
Germ-cell tumors
Other diseases
Autoimmune disorders
Amyloidosis

Timing of hematopoietic stem cell transplantation relative to diagnosis varies with disease.

AML, acute myelogenous leukemia; NHL, non–Hodgkin lymphoma.

Sources: Copelan EA. Hematopoietic stem-cell transplantation. *N Engl J Med*. 2006;354:1813–1826; Vaughan W, Seshadri T, Bridges M, Keating A. The principles and overview of autologous hematopoietic stem cell transplantation. *Cancer Treat Res*. 2009;144:23–45.

HSCT may be the only treatment available to many patients; however, it is associated with considerable morbidity and mortality, with ~40% of advanced cancer patients who undergo HSCT dying of its complications.[2] The basic schema for HSCT is illustrated in **Figure 101-1**. A combination of chemotherapy and/or radiation administered before infusion of the HSCs is referred to as the preparative or conditioning regimen.[2] The days leading up to the infusion of the HSCs are counted in the negative (ie, −3, −2, −1), the day of HSCT infusion is termed day 0, and the days following the

transplant are counted in the positive (+1, +2, etc). Although the preparative regimen may use the same agents that are used in conventional chemotherapy regimens, the doses are higher. The purpose of the preparative regimen is to eradicate the residual malignancy and, in the setting of an allogeneic HSCT, to suppress the recipient's immune system.[2] Only myeloablative preparative regimens are used for autologous HSCT; however, myeloablative, reduced-intensity or nonmyeloablative preparative regimens may be used with allogeneic HSCT. Myeloablative preparative regimens involve administration of near-lethal doses of chemotherapy and/or radiation, which ablate the BM; this may be followed by a 1- to 2-day rest. After completion of the preparative regimen, the HSCT takes place. Myeloablative preparative regimens have significant regimen-related toxicity and morbidity and thus are usually limited to healthy, younger (ie, usually younger than age 60 years) patients.[3] Alternatively, reduced-intensity or nonmyeloablative transplants are performed with the hope of curing more cancer patients without the complication of preparative-related toxicity. Nonmyeloablative regimens make use of the graft-versus-tumor (GVT) effect, allowing for donor lymphocyte-induced tumor eradication (see Graft-Versus-Host Disease section). For most chemotherapy-based preparative regimens, a rest period is necessary to allow for elimination of toxic metabolites from the chemotherapy that could damage infused cells. After chemotherapy and/or radiation, a period of pancytopenia lasts until the infused HSCs reestablish functional hematopoiesis. Engraftment, when functional hematopoiesis is established, is commonly defined as the point at which a patient can maintain a sustained absolute neutrophil count (ANC) of >500 cells/μL and a sustained platelet count of at least 20,000/μL lasting 3 consecutive days without transfusions.[4] Graft rejection occurs when the patient cannot maintain functional hematopoiesis and may occur after autologous or allogeneic HSCT.

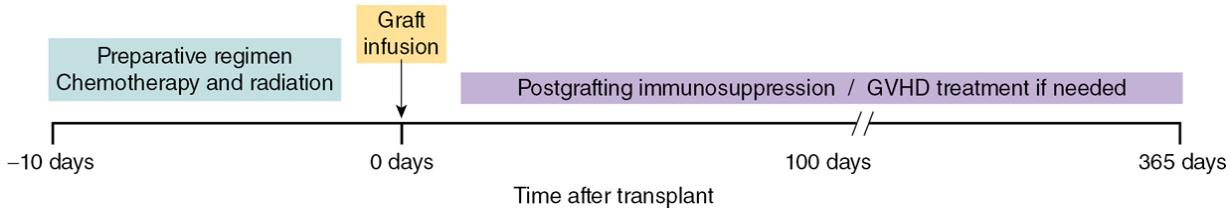

Figure 101-1 Basic schema for hematopoietic stem cell transplantation. Day 0 = bone marrow, peripheral blood progenitor cell, or umbilical cord blood infusion. Postgraft immunosuppression or graft-versus-host disease (GVHD) prophylaxis for allogeneic grafts only.

AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION

The defining characteristic of autologous HSCT is that the donor and the recipient are the same individual, making posttransplantation immunosuppression unnecessary. Autologous HSCs must be obtained (ie, harvested) before the myeloablative preparative regimen is administered and subsequently stored for administration after the preparative regimen. Essentially, these HSCs are administered as a rescue intervention to reestablish BM function and avoid long-lasting, life-threatening marrow aplasia that results from the myeloablative preparative regimen.[5] Incomplete tumor eradication by the high-intensity treatment before transplant remains the main cause of relapse after transplant.[6]

Indications for Autologous Hematopoietic Stem Cell Transplantation

CASE 101-1

QUESTION 1: P.J., a 46-year-old male, has diffuse large B-cell non–Hodgkin lymphoma (NHL) in first relapse after a complete remission of 1 year. An 80% reduction in measurable disease is noted after two cycles of dexamethasone,

high-dose cytarabine, and cisplatin (DHAP) salvage chemotherapy. P.J.'s BM biopsy and lumbar puncture are negative for malignant cells.

Is a myeloablative preparative regimen with autologous HSCT indicated for P.J.?

Autologous HSCT is used to treat a variety of malignancies (Table 101-2). NHL and multiple myeloma are the most common indications for this procedure and represent more than two-thirds of all autologous HSCT.[2] Nearly all patients who undergo autologous HSCT have failed standard chemotherapy regimens; therefore, their HSCs have been exposed to prior chemotherapy leading to less abundant and viable stem cells.

The primary use of autologous HSCT is in diseases that have aggressive features but are still chemotherapy-sensitive.[7] In a randomized, controlled trial,[8] autologous bone marrow transplant (BMT), compared with conventional chemotherapy with DHAP, resulted in a 5-year event-free survival of 46% versus 12%, respectively (P = .001). Overall 5-year survival was 53% in the BMT group and 32% in the patients undergo conventional chemotherapy (P = .038).[8]

Whereas HSCT is delayed until relapse after primary treatment in NHL, in some malignancies, autologous HSCT is indicated as primary therapy to improve overall survival and progression-free survival.[7,9,10]

Prospective studies comparing preparative regimens, stem cell mobilization techniques, and stem cell source (ie, BMT vs peripheral blood progenitor cell transplant [PBPCT]) are not available; however, autologous PBPCT has become the preferred source of stem cells, most likely owing to the improved outcomes with PBPCT in other disease settings.[11] PBPCs, defined as cells that express the CD34 antigen (eg, $CD34^+$), are continuously circulating in the blood; however, their numbers are too low to easily collect the amount needed in transplant. Mobilization refers to the techniques used to move the stem cells out of the BM compartment, increasing their numbers in circulation. Mobilization can be accomplished using

growth factors or chemotherapy (see Mobilization and Collection of Autologous Peripheral Blood Progenitor Cells section).

P.J. has minimal residual disease that has demonstrated chemotherapy sensitivity (ie, P.J. had an 80% response to chemotherapy). P.J.'s long-term prognosis will be improved with autologous PBPCT rather than with further conventional chemotherapy, as described. Thus, autologous PBPCT is indicated, owing to the greater likelihood that higher-dose chemotherapy may eradicate P.J.'s tumor.

Harvesting Autologous Hematopoietic Stem Cells

Case 101-1, Question 2: What is the best way to harvest and preserve harvested HSCs for P.J.?

PBPCs have essentially replaced BM as the source of stem cells at many HSCT centers, accounting for 98% of autologous transplants in adults from 2004 to 2008.[1] PBPCs result in more rapid engraftment than BM and fewer days of neutropenia.[12] Collection of PBPCs occurs before administering the preparative regimen; thus, autologous HSCs must be cryopreserved.[2] HSCs are frozen below −184 °F (−120 °C) and used within a few weeks; although, when frozen, they are viable for years.[2] Dimethyl sulfoxide (DMSO) is the cryopreservative commonly used to protect HSCs from damage during freezing and thawing. Infusion of HSCs stored in DMSO can be associated with toxicities because of the DMSO itself. During infusion, DMSO is associated with skin flushing, nausea, diarrhea, dyspnea, hypotension, arrhythmias, and, rarely, anaphylactic reactions.[13] The presence of undetectable tumor cells in the transplanted cells contributes to the relapse of hematologic cancers; unfortunately, purging the grafts of tumor cells does not improve survival.[2]

Relative to BM harvest, collection of PBPCs requires less invasive collection methods and contains up to five times more HSCs. This results in a PBPC HSCT having more rapid neutrophil and platelet

recovery (ie, a shorter duration of neutropenia or thrombocytopenia), fewer platelet transfusions, fewer days of intravenous antibiotics, and a shorter duration of hospitalization compared to a BM HSCT. Thus, the shift to the use of PBPCs instead of BM for autologous HSCT is primarily because of the more rapid engraftment and less invasive collection methods.[11] Therefore, it would be best for P.J. to undergo pheresis for PBPC collection. The collected cells would be bathed in DMSO and frozen at −184 °F (−120 °C).

Mobilization and Collection of Autologous Peripheral Blood Progenitor Cells

Case 101-1, Question 3: For PBPC mobilization, P.J. received one dose of cyclophosphamide 4 g/m^2 IV on day 1, followed by filgrastim 10 µg/kg/day subcutaneously (SC) beginning on day 2 and continuing through completion of pheresis. Twelve days after receiving cyclophosphamide, P.J.'s white blood cell (WBC) count recovered to 3000 cells/µL and pheresis was begun. An adequate number of PBPCs is collected after two pheresis sessions. P.J.'s cells are processed and stored. What was the rationale for administering filgrastim and cyclophosphamide? What determines the duration of pheresis?

Normally, low numbers of PBPCs are found in the peripheral circulation; therefore, it is necessary to "mobilize" PBPC from the marrow compartment into the systemic circulation. Mobilization leads to a collection of sufficient numbers of autologous PBPCs in most patients, although a minority of patients may still have poor mobilization.[11] Multiple methods can be used to mobilize PBPCs. Hematopoietic growth factors alone or in combination with myelosuppressive chemotherapy are used to mobilize PBPCs.[11] After administration of the mobilizing agent(s), the patient undergoes pheresis, an outpatient procedure similar to dialysis in order to collect PBPCs.[12]

Granulocyte–macrophage colony-stimulating factor (GM-CSF, sargramostim) and granulocyte colony-stimulating factor (G-CSF, filgrastim) are both hematopoietic growth factors and are used as mobilizing agents for PBPC collection.[11,14] Both reliably mobilize

PBPCs, with filgrastim providing a higher PBPC yield.[11] The most frequently used filgrastim doses for autologous PBPC mobilization are in the range of 10 to 24 μg/kg/day SC.[11,14] PBPC yield is higher when pheresis is started at day 5 (vs day 6), with the optimal yield being around 10 hours after filgrastim administration.[11]

Myelosuppressive chemotherapy stimulates stem cell and progenitor cell proliferation. The combination of chemotherapy with filgrastim enhances PBPC mobilization relative to filgrastim alone. A benefit of using chemotherapy is that it also treats the underlying malignancy.[11] Examples of PBPC mobilization chemotherapy regimens include single-agent cyclophosphamide or melphalan. No mobilization chemotherapy regimen is clearly superior, which has led to incorporating PBPC mobilization into a cycle of disease-specific chemotherapy, such as using a single cycle of R-ICE (rituximab, ifosfamide, carboplatin, etoposide) therapy as the mobilization regimen for an NHL patient whose disease is responsive to R-ICE treatment.[11] By administering chemotherapy to the patient, the body's repair mechanism accelerates the cell division of stem cells and releases them into the circulation. This is a delicate balance because the more the chemotherapy that is given to mobilize the stem cells, the greater the potential for damage to the stem cells and a decreased yield at collection. Stem cell toxic agents, such as carmustine, should be avoided because they lower the quantity and quality of PBPCs. The hematopoietic growth factor is initiated 24 to 72 hours after completion of chemotherapy. Pheresis begins when the peripheral WBC count recovers to greater than 1 to 3 × 10^3 cells/μL.[11]

Certain patients fail to mobilize sufficient PBPC because of extensive prior therapy or therapy with marrow toxic agents. In these patients, plerixafor, an inhibitor of the CXCR4 chemokine receptor, can be used. Plerixafor was approved by the U.S. Food and Drug Administration (FDA) in 2008 for use in stem cell mobilization in conjunction with filgrastim. It is known that CD34 is an adhesion molecule involved in promoting adherence of HSCs to the BM microenvironment. Stromal cell–derived factor-1 (SDF-1) is a chemoattractant agent for HSCs; its presence in circulation causes

rapid migration of these stem cells to the peripheral blood.[11] Inhibition of the CXCR4 by plerixafor blocks the ligand SDF-1 from binding to the CXCR4 receptor, thus releasing CD34+ cells from the BM. In two randomized studies, 59% of patients with NHL and 72% of patients with multiple myeloma had sufficient CD34+ cell collection for autologous transplant using plerixafor and filgrastim in four or fewer pheresis sessions, compared to 24% and 34%, respectively, in those using filgrastim alone.[15] Plerixafor is administered to the patient ~10 to 18 hours prior to each pheresis beginning four days after initiation of daily filgrastim 10 μg/kg. Pheresis is continued daily until the target number of PBPCs per kilogram of the recipients' weight is obtained.[11] Typically, one to two large-volume pheresis sessions are needed to collect adequate numbers of CD34+ cells.[16] For adult recipients, the number of cells infused that are CD34+ is the most reliable indicator of an adequate PBPC collection and predictor of durable engraftment.[11] A variety of different thresholds have been identified as the minimal number of CD34+ cells needed for an autologous PBPCT to produce rapid and complete (ie, WBCs, red blood cell [RBC], platelet) engraftment in adults. The minimum threshold range has varied from 1 to 3 × 10^6 CD34+ cells/kg of recipient weight, with more rapid platelet and neutrophil engraftment occurring with ≥5 to 8 × 10^6 CD34+ cells/kg of recipient weight.[11]

There are a number of factors that can affect the yield of CD34+ cells, including the timing and amount of myelosuppressive treatments received before mobilization; both chemotherapy and radiation negatively impact mobilization. The type of chemotherapy, number of different regimens, and overall duration of chemotherapy treatment affect the ability to collect stem cells. Additionally, hypocellular marrow and refractory disease can lead to a poor PBPC harvest.[11] There is a paucity of information regarding the parameters associated with engraftment in children undergoing an autologous PBPCT.[17] After pheresis, the cells are cryopreserved, stored, thawed, and infused into the patient as described in the Harvesting Autologous HSCs section. Because P.J. has been in remission for a year after initial treatment for his disease, he received no radiation

treatment, and his salvage therapy did not contain alkylating agents, his cell collection can be expected to be good and of short duration.

Myeloablative Preparative Regimens

CASE 101-1, QUESTION 4: What are the goals and characteristics of agents used for myeloablative preparative regimens in patients like P.J.?

The primary goal of P.J.'s high-dose, myeloablative preparative regimen followed by autologous transplant is to eradicate residual malignancy that is not treatable with standard chemotherapy. With autologous HSCT, there is no need for immunosuppression because the donor and recipient are genetically identical.[2] Combination chemotherapy with multiple alkylating agents constitutes the most common high-dose regimens before autologous HSCT. Alkylating agents are used because they exhibit a steep dose–response curve for various malignancies to overcome resistance to treatment and are characterized by dose-limiting BM suppression.[18] Ideally, combinations of antineoplastics should have nonhematologic toxicities that do not overlap and that are not life-threatening. Examples of common myeloablative regimens are illustrated in **Table 101-3**.[19–23] The early and late toxicities to myeloablative regimens are listed in **Table 101-4**.[2–4]

Table 101-3
Representative Myeloablative Preparative Regimens Used in Hematopoietic Stem Cell Transplantation

Type of HSCT	Disease State	Regimen	Dose/Schedule
Allogeneic[75]	Hematologic malignancies[a]	CY/TBI	CY 60 mg/kg/day IV on 2 consecutive days before TBI 1000–1575 rads fractionated for 1–7 days
Autologous[92,93]	Acute and chronic leukemias	BU/CY	BU adult 1 mg/kg/dose PO or 0.8 mg/kg/dose IV every 6 hours for 16 doses
			BU children >12 kg, 1.1 mg/kg/dose IV every 6 hours for 16 doses
			CY 50 mg/kg/day IV daily for 4 days or 60 mg/kg/day IV daily for 2 days after BU
Autologous[23]	Non–Hodgkin lymphoma, Hodgkin disease	BEAM (carmustine/etoposide/cytarabine/melphalan)	Carmustine 300 mg/m^2/day IV, 1 dose
			Etoposide 200 mg/m^2/day bid IV for 3 days
			Cytarabine 200 mg/m^2/day IV bid for 4 days
			Melphalan 140 mg/m^2 1 dose

bid, twice a day; BU, busulfan; CY, cyclophosphamide; IV, intravenously; PO, orally; TBI, total body irradiation.

[a]Includes acute myelogenous leukemia (AML), acute lymphocytic leukemia, chronic myelogenous leukemia, non–Hodgkin lymphoma, and Hodgkin disease.

Table 101-4

Common Toxicities Associated With Myeloablative Allogeneic Hematopoietic Stem Cell Transplantation

Early Posttransplant (<100 days)	Late Posttransplant (>100 days)
Febrile neutropenia	Increased susceptibility to infections
Nausea, vomiting, diarrhea Mucositis Veno-occlusive disease Renal dysfunction Cardiotoxicity	Endocrine disorders (hypothyroidism, hemorrhagic cystitis, infertility, growth retardation) Neurocognitive changes
Pneumonitis	Secondary malignant neoplasms
Graft rejection	Chronic GVHD
Acute GVHD	Cataracts

GVHD, graft-versus-host disease.

Complications of Autologous Hematopoietic Stem Cell Transplantation

Case 101-1, Question 5: What complications must be anticipated as a consequence of autologous HSCT? How can these be minimized? How can treatment be provided in an outpatient setting?

The most common cause of death after autologous HSCT is relapse of the primary disease. The most common toxicities seen during autologous HSCT are the result of the pancytopenia induced by high-dose chemotherapy. Because autologous HSCT is not complicated by profound immunosuppression or graft- versus-host

disease (GVHD), supportive-care strategies differ from allogeneic HSCT. Isolation and use of laminar airflow rooms are unnecessary. The use of autologous peripheral blood stem cell transplantation (PBSCT) is associated with shorter periods of neutropenia and less need for clinical resources; thus, some HSCT centers have developed programs that incorporate outpatient care into the initial recovery. These outpatient programs also offer cost savings to the payer for health services.[24,25] Successful outpatient care during autologous HSCT requires careful development and implementation of the necessary supportive-care strategies to prevent or minimize infection, chemotherapy-induced nausea and vomiting, infection, pain, and transfusion requirements. It is also necessary to develop admission criteria for patients with more severe complications.

Use of prophylactic oral antibiotics and once-daily IV antibiotics to prevent or treat febrile neutropenia has facilitated outpatient care and prevented select patients from being hospitalized.[26]

In addition, outpatient care during autologous HSCT demands that HSCT centers have appropriate resources, facilities, and staff to provide 24-hour patient care coverage. Patients undergoing outpatient care must meet eligibility criteria, including the availability of caregivers 24 hours a day and housing within close proximity to the HSCT center.

Hematopoietic Growth Factors After Autologous Peripheral Blood Progenitor Cell Infusion

Case 101-1, Question 6: Ten days after the collection of PBSC, P.J. is admitted for his autologous HSCT. He receives a myeloablative preparative regimen with cyclophosphamide, carmustine, and etoposide with an autologous PBPC graft. An order is written to begin filgrastim 5 µg/kg/day SC, beginning on day 5 and continuing until the ANC has recovered to 500 cells/µL for 3 consecutive days. What is the rationale for filgrastim in P.J. after the transplant procedure?

Autologous HSCTs, regardless of the stem cell source, are associated with profound aplasia because of the myeloablative preparative regimen (Table 101-3). Aplasia typically lasts 14 to 21 days after an autologous BMT and 10 to 14 days after an autologous PBPCT.[21] During this period of pancytopenia, patients are at high risk for complications such as bleeding and infection. To lessen the complications of pancytopenia, hematopoietic growth factors, such as filgrastim and sargramostim, may be used. These drugs exert their effects by stimulating the proliferation of committed progenitor cells. The benefits of the hematopoietic growth factor have been shown in several large multicenter, randomized, double-blind, placebo-controlled trials.[27–29] The majority of the trials suggest hematopoietic growth factor administration is associated with a shorter time to neutrophil engraftment (by 4–7 days), less infectious complications, shorter hospitalization after autologous BMT, and therefore decreased resource utilization.[27,28,30] However, the use of these agents does not affect overall survival.[27,29]

Although studies in the autologous PBPCT setting note more rapid neutrophil recovery after hematopoietic growth factor use, others report no difference in infection rates and minimal decreases in associated resource use such as the duration of hospitalization.[28,30–32] Although clinical practice guidelines for hematopoietic growth factors support their use after autologous transplant, pharmacoeconomic analyses are needed to further evaluate the true benefit of hematopoietic growth factors after autologous PBPCT.

Filgrastim is preferred for accelerating neutrophil engraftment in clinical practice. The reason most commonly cited is the desire to avoid febrile reactions associated with sargramostim, which complicates the interpretation of febrile neutropenia. Although sargramostim or filgrastim theoretically may stimulate proliferation of leukemia myeloblasts, no evidence to date suggests that the incidence of leukemia relapse is higher in patients who receive these hematopoietic growth factors after autologous or allogeneic HSCT.[33,34]

Although both filgrastim and sargramostim successfully hasten neutrophil recovery, neither agent stimulates platelet production or

augments platelet recovery.[27,28] At this time, there is no established role for erythropoietin-stimulating agents or platelet growth factors in the care of these patients. In summary, P.J. is undergoing autologous PBPCT for the treatment of lymphoid malignancy. Thus, either sargramostim or filgrastim is an acceptable option for accelerating engraftment. Whether the addition of either agent will reduce infection and improve other clinically relevant outcomes is debatable.[14] A complete blood cell (CBC) count with differential should be obtained daily. Filgrastim should be continued until neutrophil recovery is achieved.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Allogeneic HSCT involves the transplantation of HSCs obtained from a donor's BM, PBPCs, or umbilical cord blood to a patient. Fifty-one percent of all transplants performed in North America in 2008 used unrelated donors.[1] Thus, to understand the application of and complications after allogeneic HSCT, a working knowledge of immunology and the major histocompatibility complex (MHC) and human leukocyte antigen (HLA) in humans is necessary.

Indications for Allogeneic Hematopoietic Stem Cell Transplantation

CASE 101-2

QUESTION 1: B.S., a 22-year-old male, has acute myelogenous leukemia (AML) in first remission after induction chemotherapy with standard doses of cytarabine and daunorubicin and consolidation with high-dose cytarabine. B.S. has poor-risk cytogenetics, with abnormalities of 11q23 and inversion 3. Thus, he will receive an allogeneic HSCT as part of postremission therapy. Typing performed on family members has identified a fully HLA-matched sibling donor. B.S. returns to the clinic today for a pretransplant workup. At this time, his

physical examination is noncontributory. All laboratory values are within normal limits. A BM biopsy reveals <5% blasts. B.S. has a normal electrocardiogram and cardiac wall motion study. His renal, hepatic, and pulmonary function tests are normal.

Is an allogeneic HSCT indicated for B.S.?

The primary indications for allogeneic HSCT include treatment of otherwise fatal diseases of the BM or immune system (Table 101-2). The optimal role and timing of allogeneic HSCT, in contrast to other therapies, remains controversial,[35] especially because treatment options for AML have increased. The National Comprehensive Cancer Network treatment guidelines for AML include the use of allogeneic HSCT. A matched sibling or alternative donor (eg, matched-unrelated donor [MUD]) HSCT is recommended as part of postremission therapy in patients with preceding hematologic disease (eg, myelodysplasia, secondary AML) or poor-risk cytogenetics, as in the case of B.S.[36] Current research efforts focus on the use of reduced-intensity preparative regimens and the utility of HSCT relative to novel targeted agents in the hope of improving the outcome of allogeneic HSCT.[36] B.S. is eligible for allogeneic HSCT by virtue of his cytogenetics and the availability of a histocompatible donor. In addition, he meets age and organ function eligibility requirements and is in complete remission with minimal residual disease.

Histocompatibility

Case 101-2, Question 2: Why is histocompatibility important in the selection of the donor in patients like B.S. who undergo an allogeneic HSCT?

Because the tissue transplanted in allogeneic HSCT is immunologically active, there is potential for bidirectional graft rejection.[2] In the first scenario, cytotoxic T cells and natural killer (NK) cells belonging to the host (recipient) recognize MHC antigens of the graft (donor HSCs) and elicit a graft rejection response. This

results in ineffective hematopoiesis (ie, inadequate ANC and/or platelet counts) posttransplant. In the second scenario, immunologically active cells in the graft recognize host MHC antigens and elicit an immune response, referred to as GVHD. Therefore, an essential first step for patients eligible for HSCT is finding an HLA-compatible graft with an acceptable risk of rejection and GVHD.

Determination of histocompatibility between potential donors and the patient is completed before allogeneic HSCT.[37] Initially, HLA typing is performed using tissue (buccal swab) and blood samples. Compatibility at class I MHC antigens (HLA-A, HLA-B, and HLA-C) is determined through serologic and DNA-based testing methods.[38,39] Currently, most clinical and research laboratories are also performing molecular DNA typing.[38–47] A donor–recipient pair with different HLA antigens (ie, "antigen mismatched") always has different alleles, whereas pairs with the same allele always have the same antigen and are termed "matched." However, some pairs have the same HLA antigen but different alleles and are thus "allele mismatched" (see Chapter 34, Kidney and Liver Transplantation, for additional discussion of histocompatibility).

Graft rejection is least likely to occur with a syngeneic donor, meaning that the recipient and host are identical (monozygotic) twins. Identical twins occur spontaneously in nature in ~1 in 100 births; thus, it is unlikely that a patient would have a syngeneic donor. In those patients without a syngeneic donor, initial HLA typing is conducted on family members because the likelihood of a complete histocompatibility match between unrelated individuals is remote. Siblings are the most likely to be histocompatible within a family; however, only 25% of potential HSCT recipients will have an HLA-identical sibling.[38]

Lack of an HLA-matched sibling donor can be a barrier to allogeneic HSCT. Alternative sources of allogeneic HSCs, such as related donors mismatched at one or more HLA loci, or MUDs, are used.[40] Establishment of the National Marrow Donor Program has helped increase the pool of potential donors for allogeneic HSCT.[40] Through this program, an HLA-matched-unrelated volunteer donor

might be identified. Recipients of an unrelated graft are more likely to experience graft failure and acute GVHD (aGVHD) relative to recipients of a matched sibling donor.[41] Thus, work is ongoing to identify factors that predict graft failure or GVHD to improve the availability and safety of unrelated donor transplants (see Graft Rejection section).[42] Recently, work has focused on a set of predictive biomarkers that help stratify patients' risk for GVHD. On day 7 of allogeneic HSCT, a two-biomarker panel of ST2 and REG3a is sent from the peripheral blood. These biomarkers, which help assess patient reaction to donor histocompatibility antigens and donor T-cell response to alloantigens, predicted likelihood of developing GVHD and nonrelapse mortality.[43,44]

The preparative regimen and/or GVHD prophylaxis may be altered based on the mismatch between the donor and the recipient. The risk of graft failure decreases with better matches, and although mismatching in a single HLA allele does not appear to impact overall survival, mismatching in more than one allele significantly impairs overall survival. The most important alleles to match are the HLA class I antigens (HLA-A, HLA-B, HLA-C) and the HLA class II antigens (HLA-DRB1, HLA-DPB1, HLA-DQB1).[45–47] This field is continually evolving with current data suggesting that mismatches at HLA-DPB1 confer an increased risk of mortality.[48]

Eligibility criteria for allogeneic HSCT vary between institutions. Having a matched sibling donor is no longer a requirement for allogeneic HSCT because improved immunosuppressive regimens and the National Marrow Donor Program have allowed an increase in the use of unrelated or related matched or mismatched HSCT.[41] Potential donors also include haploidentical donors, who are a parent, sibling, or child of a parent with only one identical HLA haplotype. Hematopoietic cell transplant with a haploidentical donor was initially associated with high rates of graft failure and GVHD, but recent technologic advances have improved outcomes. Haploidentical HSCT involves another alloreactive mechanism involving NK cells, which may be associated with reduced relapse rates in patients with AML.[2]

Normal renal, hepatic, pulmonary, and cardiac functions are necessary for eligibility at most centers. Historically, patients age older than 55 years were excluded from allogeneic HSCT because they were more likely to succumb to transplantation-related complications. However, many centers are now considering patients up to 65 years old and basing their selection criteria on physiologic rather than biologic age.

Harvesting, Preparing, and Transplanting Allogeneic Hematopoietic Stem Cells

Case 101-2, Question 3: What methods can be used to harvest HSCs from B.S.'s histocompatible sibling and prepare them for transplant? Are there any advantages to the use of BM, PBPCs, or umbilical cord blood as a source for HSCs?

The method of harvesting allogeneic HSCs varies according to the site of harvest (ie, BM, peripheral blood, or umbilical cord blood). ABO incompatibility increases the complexity of HSCT but is not an obstacle to HSCT. The HSCs may need additional processing to reduce the RBCs infused with the HSCT product if the donor and recipient are ABO-incompatible, which occurs in 30% to 40% of sibling donor HSCTs and is higher in unrelated donor HSCT.[49] Various strategies posttransplant used to manage blood support for ABO-incompatible HSCT recipients include the infusion of donor-type fresh frozen plasma to provide a noncellular source of A or B antigens, as well as transfusing-type volume-reduced RBCs and platelets or O RBCs to minimize the risk of immune-mediated hemolytic anemia and thrombotic microangiopathic syndromes.[49]

BONE MARROW

Harvesting BM entails a surgical procedure in which marrow is obtained from the iliac crests. Allogeneic BM is obtained from the donor under local or general anesthesia on day 0 of BMT.[2] The number of nucleated marrow cells harvested varies depending on

the disease being treated, conditioning regimen, and preinfusion manipulation and is usually 1 to 3 × 10^8 infused cells/kg of recipient weight.[17] These cells are obtained through multiple aspirations of marrow from the posterior iliac crests. The marrow is then processed to remove fat or marrow emboli and is usually immediately infused intravenously into the patient. If immediate transplant is not possible, the BM is frozen until it can be infused. Once infused into circulation, through the mechanism of the chemokine SDF-1/CXCR4 receptor, the stem cells migrate to the BM compartment where they will eventually reside.

PERIPHERAL BLOOD PROGENITOR CELLS

As mentioned, HSCs continuously detach, enter the circulation, and return to the marrow; thus, the peripheral blood is a convenient source of HSCs. The number of PBPCs is estimated by using the cell-surface molecule CD34 as a surrogate marker. The number of circulating CD34+ cells in blood is increased by mobilizing them from the marrow. The most commonly used regimen to mobilize allogeneic (healthy) donors is a 4- to 5-day course of filgrastim 10 to 16 μg/kg/day SC, followed by pheresis on the fourth or fifth day when peripheral blood levels of CD34+ cells peak.[9] An adequate number of HSCs is usually obtained with one to two pheresis collections. The optimal number of CD34+ required is 4 to 10 × 10^6 cells/kg of recipient body weight for an HLA-identical sibling donor transplant with haploidentical transplants requiring greater numbers.[10,50,51] Higher cell doses have been associated with not only more rapid engraftment but also fewer fungal infections and improved overall survival.[52] HSCs obtained from the peripheral blood are processed like BM-derived stem cells and may be infused immediately into the recipient or frozen for future use. Compared to BM, PBPC infusions are associated with quicker neutrophil and platelet engraftment.[2] In patients with a hematologic malignancy and a matched sibling donor, PBPCT is also associated with lower relapse rates and increased disease-free survival rates.[53] However, PBPC grafts contain more T cells than do BM grafts.[2] Therefore,

PBPCT has a similar incidence of aGVHD, but an ~20% higher incidence of extensive stage and overall chronic GVHD (cGVHD).[53]

UMBILICAL CORD BLOOD

Blood from the umbilical cord and the placenta is rich in HSCs but limited in volume.[54] Thus, umbilical cord blood offers an alternative stem cell source to those patients who do not have a suitable related donor. After consent is obtained, the cord blood cells are obtained in the delivery room after birth, typically after the delivery of the placenta.[55]

The cord blood is then processed, and, if it matches certain preestablished criteria (eg, minimum nucleated cell content, sterility), a sample is sent for HLA typing and cryopreserved for future use. An estimated 20,000 HSCTs with cord blood donors have been performed with >300,000 cord blood units banked worldwide. It is unknown how long cryopreserved cord blood is viable.[56]

HSCT with an unrelated cord blood donor has several potential advantages over unrelated marrow or PBPC donors.[54] Specifically, (a) cord blood is readily available, which leads to a more rapid time to HSCT; (b) lack of stem cell exposure to the thymus allows for greater degrees of HLA disparity as compared to BM or PBPC[55]; and (c) despite the less-stringent HLA matching, mismatched cord blood cells are less likely to cause GVHD while still maintaining GVT activity. The less-stringent HLA requirements increase the likelihood of identifying a suitable allogeneic donor, which is particularly beneficial for minority populations who are underrepresented in adult registries and often lack matched stem cell sources. Outcomes in umbilical cord blood recipients are improved with fewer HLA mismatches and greater numbers of CD34+ cells.[57] However, the limited number of HSCs in cord blood is a disadvantage, in particular when considering adult patients.[58] In order to overcome the cell dose limitation and improve engraftment, researchers have been studying infusing two cord blood units,[59] coinfusing a cord blood unit with highly purified CD34+ cells from haploidentical donors,[60] and ex vivo expansion of cord blood progenitors,[61] delivery of the cord blood unit

directly into the BM space,[62–64] and priming of cord blood with agents that may facilitate homing to the BM.[65]

As an adequate cell dose is critical for engraftment after cord blood transplantation and the cell dose of a single cord blood unit is limited, progress in the field of cord blood transplantation for the treatment of adults has been slower.[58] However, recent data showed that when a single cord blood unit with an adequate cell dose is available, the outcomes of adults with leukemia are similar to those receiving unrelated BM or peripheral blood grafts.[66]

Moreover, for those adults with leukemia who do not have a single cord blood unit with a suitable cell dose, the use of two partially matched cord blood units to compose the graft also provides outcomes similar to that of related and unrelated donors.[67] These data associated with the promising outcomes when using umbilical cord blood in the context of reduced-intensity conditioning have significantly increased the utilization of cord blood as a source of hematopoietic progenitors for the treatment of adult patients.[68,69]

In summary, the utilization of cord blood as a source of HSCs for transplantation has substantially expanded in the last decade. Novel methodologies to improve engraftment, promote immune reconstitution, and improve outcomes after cord blood transplantation are under investigation and are likely to further extend its availability to patients who require a potentially curative allogeneic transplant but lack a suitable related donor.

Therefore, it is most reasonable to harvest PBPCs from B.S.'s sibling to use for his myeloablative HSCT because his sibling is fully HLA-matched. A PBPC transplant is preferred to BMT because of the expectations of increased speed of neutrophil and platelet engraftment and disease-free survival rate and lower relapse rate.

GVT Effect

Case 101-2, Question 4: B.S. will receive an allogeneic HSCT from his histocompatible sibling with the hope of inducing GVT effect to help in treating

his malignancy. What is the GVT effect? Which tumors are most responsive to this effect?

GVT refers to the phenomenon where the donor's cytotoxic T lymphocytes suppress or eliminate the recipient's malignancy. Initial clinical evidence of a GVT effect came from the observation that patients with GVHD had lower relapse rates compared with those who did not.[70,71] This suggested a GVT effect because of the donor lymphocytes. Lymphocyte involvement in GVT was further supported by the effectiveness of donor lymphocyte infusions in treating patients who experienced relapse of their malignancies after allogeneic HSCT.[72,73] Eradication of the recurrent malignancy is because of either specific targeting of the tumor antigens or to GVHD, which may affect cancer cells preferentially. Different illnesses vary in their responsiveness to donor lymphocyte infusions, with chronic myelogenous leukemia (CML) and acute leukemias being the most and least responsive, respectively.[74] Patients with certain solid tumors (eg, renal cell carcinoma) also appear to benefit from a GVT effect.[75] These data are the platform on which the use of reduced-intensity and nonmyeloablative preparative regimens are based.

Preparative Regimens for Allogeneic Hematopoietic Stem Cell Transplantation

MYELOABLATIVE PREPARATIVE REGIMENS

Case 101-2, Question 5: What is the rationale for using myeloablative preparative regimens for patients like B.S. who are to receive an allogeneic HSCT? What types of regimens are used and what is recommended for B.S.?

The combination of chemotherapy and/or radiation used in allogeneic HSCT is referred to as the preparative or conditioning regimen. The rationale for high-dose myeloablative preparative regimens is similar to that discussed in the Autologous HSCT

section. Infusion of HSCs restores hematopoiesis induced by dose-limiting myelosuppression of chemotherapy, maximizing the potential value of the steep dose–response curve to alkylating agents and radiation,[18] and suppressing the host immune system. The preparative regimen is also designed to eradicate immunologically active host tissues (lymphoid tissue and macrophages) and to prevent or minimize the development of host-versus-graft reactions (ie, graft rejection). Conversely, patients undergoing syngeneic transplantation do not require immunosuppressive preparative regimens before HSCT because the donor and the patient are genetically identical; thus, there is no potential for host-versus-graft reactions. Therefore, preparative regimens are tailored to the primary disease and to HLA compatibility between the recipient–donor pair.

Examples of common preparative regimens for allogeneic HSCT are shown in Table 101-3.[8,20,76] Table 101-4 lists the common toxicities associated with myeloablative allogeneic HSCT. Most allogeneic preparative regimens for the treatment of hematologic malignancies contain cyclophosphamide, radiation, or both. The combination of cyclophosphamide and total body irradiation (TBI) was one of the first preparative regimens used, and it is still used widely today. This regimen is immunosuppressive and has inherent activity against hematologic malignancies (eg, leukemias, lymphomas). TBI is myeloablative and immunosuppressive, does not have cross-resistance to chemotherapy, and reaches sites not affected by chemotherapy (eg, the central nervous system).[2] The toxicity of TBI and the scarcity of facilities for its delivery have led to the development of radiation-free preparative regimens. Modifications of the cyclophosphamide–TBI (CY/TBI) preparative regimen include replacing TBI with other agents such as busulfan and adding other chemotherapeutic or monoclonal agents such as alemtuzumab to the existing regimen. These measures are designed to minimize the long-term toxicities associated with TBI (eg, growth retardation in children, cataracts) or to provide additional antitumor activity. The long-term outcomes of busulfan/cyclophosphamide (BU/CY) and CY/TBI in patients with AML and CML have been

compared in a meta-analysis of four clinical trials.[77] Equivalent rates of long-term complications were present between the two preparative regimens, except for a greater risk of cataracts with CY/TBI and alopecia with BU/CY. Overall, disease-free survival rates were similar in patients with CML, although there was a trend for improved disease-free survival with CY/TBI in patients with AML. In the case of a mismatched allogeneic HSCT with an increased chance of graft rejection, antithymocyte globulin (ATG) may also be added to the preparative regimen to further immunosuppress the recipient.

Based on these data, the CY/TBI preparative regimen is preferred for B.S. because he has AML with poor cytogenetics and has a matched sibling available. Because of the high relapse rates seen in AML, myeloablative allogeneic transplant is indicated in first remission for patients younger than 60 years old with good performance status because of the decrease in the likelihood of achieving a complete response to reinduction chemotherapy and the expected reduced duration of a second remission.

REDUCED-INTENSITY OR NONMYELOABLATIVE PREPARATIVE REGIMENS

Case 101-2, Question 6: Describe the rationale for nonmyeloablative preparative regimens. Is B.S. a candidate for such a regimen?

The regimen-related toxicity of a myeloablative preparative regimen (Table 101-4) limits the use of allogeneic HSCT to younger patients who have minimal comorbidities. Because many patients with hematologic malignancies are older and have comorbidities, myeloablative HSCT cannot be offered to a substantial portion of them.[78] The observation that patients with GVHD have less relapses and an improved understanding of the GVT effect led to the development of strongly immunosuppressive but not myeloablative (ie, a reduced-intensity or nonmyeloablative) preparative regimens.[2] Currently, reduced-intensity preparative regimens account for 30% of

allogeneic transplants.[79] More than 60% of patients receiving reduced-intensity preparative regimens are older than 50 years.[1,79]

There is a wide spectrum of reduced-intensity preparative regimens, with the nonmyeloablative regimens causing the least amount of myelosuppression. In general, more intensive preparative regimens are required for engraftment in the setting of unrelated donor or HLA-mismatched–related HSCT.[80] Reduced-intensity regimens do not completely eliminate the host's normal hematologic and malignant cells and, therefore, depend on the GVT effect to eradicate remaining cancer. The newly transplanted donor cells slowly replace host hematopoiesis and elicit GVT effects.[75] After engraftment, mixed chimerism is generally present. Chimerism can be defined as the ability to detect both donor-derived and recipient-derived hematopoietic cells; both donor and patient cells coexist together for a period of time in the patient. If the graft is rejected, typically only recipient cells are present. After a reduced-intensity preparative regimen, mixed chimerism (defined as 5%–95% donor T cells present in the peripheral blood) between the host and recipient develops, allowing for a GVT effect as the primary form of therapy. Chimerism is evaluated to monitor disease response and engraftment posttransplant. Chimerism is assessed within T cells and granulocytes in the peripheral blood and BM using conventional (eg, using sex chromosomes for opposite sex donors) and molecular (eg, variable number of tandem repeats for same-sex donors) methods. The methods used to characterize chimerism after HSCT are reviewed elsewhere.[81–83] A few months after HSCT, donor lymphocytes can be infused (called a "donor lymphocyte infusion") to augment the GVT activity.[2] The use of donor lymphocyte infusions is dependent on the availability of the donor and is highly center-specific. The challenge is to maximize the GVT effect while minimizing the risk of GVHD. Therefore, GVHD prophylaxis, although different from that used with myeloablative regimens, is still necessary. Although reduced-intensity preparative regimens have led to lower treatment-related mortality rates, they may be offset by higher relapse rates.[2,84] The safety and efficacy of these regimens have led to their wider application to nonmalignant conditions.[2]

Because most of the data for reduced-intensity preparative regimens are derived from older patients or those with comorbid conditions, they cannot be compared with data for myeloablative preparative regimens.[84] It is unclear if reduced-intensity preparative regimens improve long-term survival of patients with malignant or nonmalignant diseases who are younger or without comorbid conditions. Prospective controlled trials are needed with stratification based on comorbidities, disease characteristics, pretransplant therapy, and hematopoietic stem cell source.[84]

There is a paucity of data regarding the optimal source of HSCs after reduced-intensity preparative regimens. Most case series have combined data from PBPC and marrow grafts. But some data suggest that, compared to BM grafts, PBPC is associated with quicker engraftment, earlier T-cell chimerism, longer progression-free survival, and a lower risk of graft rejection.[85,86]

B.S. is young and healthy enough to receive a myeloablative allogeneic HSCT. Presently, reduced-intensity HSCT is only indicated as first-line therapy for patients ineligible for myeloablative regimens because of age, extensive prior treatments, or other contraindications. It is not an option for B.S.

Posttransplantation Immunosuppressive Therapy

Case 101-2, Question 7: What is the rationale for immunosuppressive therapy after an allogeneic HSCT? What is recommended for B.S.?

After infusion of HSCs, immunosuppressive therapy is administered to prevent or minimize GVHD. Patients receiving syngeneic transplants or a T-cell–depleted histocompatible allogeneic transplant generally do not receive posttransplantation immunosuppressive therapy. In syngeneic transplantation, the donor and the patient are genetically identical, and GVHD should not be elicited. In T-cell–depleted transplantation, the volume of donor T cells infused into the patient is usually insufficient to elicit significant GVHD.[72,87] Numerous immunosuppressive agents given alone or in

combination have been evaluated for the prevention of GVHD. Commonly used regimens after myeloablative HSCT include cyclosporine or tacrolimus administered with a short course of low-dose methotrexate.[88] GVHD prophylaxis varies in reduced-intensity protocols and can be found in **Table 101-5**.[89] Corticosteroids may also be used to prevent GVHD, but they are more commonly used to treat GVHD. In allogeneic HSCT recipients without GVHD, immunosuppressive therapy is slowly tapered and discontinued over the course of 6 months to 1 year. Over time, the immunologically active tissue between host and recipient become tolerant of one another and cease recognizing the other as foreign, negating the need for immunosuppression. In contrast, solid-organ transplant recipients usually continue immunosuppressive therapy for the duration of the recipient's life.

Table 101-5

Common Reduced-Intensity Preparative or Nonmyeloablative Regimens and Postgrafting Immunosuppression

Preparative Regimens	Postgraft Immunosuppression
Fludarabine 30 mg/m^2/day IV on 3 consecutive days (−4, −3, −2), TBI 2 Gy as a single fraction on day 0	Cyclosporine 6.25 mg/kg PO bid, day –3 to day +100 with taper from days +100 to +180
Fludarabine 25 mg/m^2/day IV for 5 days and melphalan 90 mg/m^2/day IV for 2 days	Mycophenolate mofetil 15 mg/kg PO bid or tid, days +0 to +40 with taper from days +40 to +90
Fludarabine 25–30 mg/m^2/day IV for 3–5 days, busulfan ≤9 mg/kg/total dose	Tacrolimus to maintain trough blood concentration of 5–10 ng/mL with methotrexate 5 mg/m^2/day IV days +1, +3, +6, +11

bid, two times a day; IV, intravenous; PO, orally; TBI, total body irradiation; tid, three times a day.

Source: Ren S, Kalhorn TF, McDonald GB, Anasetti C, Appelbaum FR, Slattery JT. Pharmacokinetics of cyclophosphamide and its metabolites in bone marrow transplantation patients. *Clin Pharmacol Ther*. 1998;64:289–301.

In patients without a matched-related or matched-unrelated donor who undergo HSCT with a haploidentical donor, the use of

cyclophosphamide posthematopoietic stem cell infusion may be used. The cyclophosphamide is typically given ~4 days after HSCT. It has been shown that the cyclophosphamide does not affect the HSCs but does exert its effect on alloreactive T cells, thereby reducing the risk of GVHD development.[90] Current trials are ongoing to assess the usefulness of this approach.

B.S. is receiving a myeloablative preparative regimen with allogeneic transplant and will receive cyclosporine administered for 6 months, followed by a taper, with a short course of methotrexate 15 mg/m^2 on day +1 and 10 mg/m^2 on day +3, +6, and +11 for posttransplant immunosuppression. This combination regimen will lower the risk of GVHD. Assuming B.S. does not experience any serious complications, he will likely be immunosuppressant free by 9 months posttransplant. The cyclosporine will require therapeutic drug monitoring.

Comparison of Supportive-Care Strategies Between Autologous and Allogeneic Myeloablative Hematopoietic Stem Cell Transplantation

Case 101-2, Question 8: How do supportive-care strategies used for myeloablative preparative regimens with an autologous graft differ from an allogeneic graft? What supportive care will B.S. likely require?

Supportive-care strategies common to patients receiving a myeloablative preparative regimen, regardless of whether they have received an autologous or allogeneic HSCT, include use of indwelling central venous catheters; blood product support; and pharmacologic management of chemotherapy-induced nausea and vomiting, mucositis, and pain. These similarities are a function of the side effects of a myeloablative preparative regimen.

Because of the different needs for immunosuppression with an autologous and allogeneic HSCT, the supportive care differs.

Patients undergoing allogeneic HSCT experience an initial period of pancytopenia followed by a more prolonged period of immunosuppression, which substantially increases the risk of bacterial infections, but more importantly, fungal, viral, and other opportunistic infections.[4] The risk of infection increases as additional immunosuppressive therapy is incorporated to prevent or treat GVHD. Supportive strategies designed to minimize infection during immunosuppression are essential after allogeneic HSCT (see Infectious Complications section).

B.S. received a myeloablative allogeneic transplant; therefore, he will have a central venous catheter inserted at admission. He will most likely require multiple RBC and platelet transfusions until engraftment occurs. He is at increased risk of infection because he will be immunosuppressed for months after the transplant. Also, if he were to develop GVHD, additional supportive care would be required. GVHD prophylaxis with cyclosporine and methotrexate will place him at risk for additional drug-related toxicities that will require monitoring. Had he received an autologous transplant the duration of neutropenia would be less, no immunosuppressive medications would be required, and the risk of developing complications from GVHD would have been avoided.

Comparison of Supportive-Care Strategies Between Allogeneic Myeloablative and Nonmyeloablative Hematopoietic Stem Cell Transplantation

Case 101-2, Question 9: How do supportive-care strategies used for myeloablative and nonmyeloablative preparative regimens with an allogeneic graft differ?

A direct comparison of the toxicities between a myeloablative and nonmyeloablative preparative regimen is difficult because the latter is offered only to patients who are not candidates for myeloablative

allogeneic HSCT. The preparative regimens differ substantially in terms of the chemotherapy agents used (Tables 101-3 and 101-5) and the degree of myelosuppression. Nonmyeloablative HSCT may have a different time pattern for infectious complications, but there is a similar incidence and severity of aGVHD. This makes comparisons between the preparative regimens challenging because of the differences in the pre-HSCT health of the recipients.[80] Clinical research is focusing on designing optimal preparative regimens with acceptable efficacy and toxicity. Thus, as compared to myeloablative HSCT, the preparative regimens and immunosuppression used after hematopoietic stem cell infusion are more variable for reduced-intensity and nonmyeloablative HSCT.

Complications Associated with Hematopoietic Stem Cell Transplantation

CASE 101-3

QUESTION 1: K.M. is a 36-year-old female with CML in accelerated phase. After her initial diagnosis, a successful search for an unrelated 6/6 HLA-matched allogeneic donor was conducted. K.M. is being admitted for myeloablative allogeneic PBPCT. Orders for K.M.'s preparative regimen are written as follows: busulfan, 16 mg/kg total dose to be administered over 4 days (1 mg/kg/dose orally [PO] every 6 hours for 16 doses, days −7, −6, −5, and −4). Cyclophosphamide 60 mg/kg/day IV to be administered on days −3 and −2. Day −1 is a "rest" day, followed by infusion of PBPC on day 0.

What toxicities associated with myeloablative preparative regimen should be anticipated in K.M.? Are they similar to those anticipated after standard-dose chemotherapy?

Myelosuppression is a frequent dose-limiting toxicity for chemotherapy when administered in conventional doses used to treat cancer. However, because myelosuppression is circumvented with hematopoietic rescue in the case of patients receiving HSCT, the dose-limiting toxicities of these myeloablative preparative

regimens are nonhematologic (ie, extramedullary) in nature. The toxicities vary with the preparative regimen used. Most patients undergoing HSCT experience toxicities commonly associated with chemotherapy, such as alopecia, mucositis, chemotherapy-induced nausea and vomiting, infertility, and pulmonary toxicity (see Chapter 94, Adverse Effects of Chemotherapy, Immunotherapy, and Targeted Agents). However, these drug-related toxicities are magnified in the HSCT population.

Table 101-4 depicts a range of toxicities that can occur after myeloablative preparative regimen for HSCT, and **Figure 101-2** depicts the time course for complications after HSCT. Selected toxicities are discussed in the following sections.

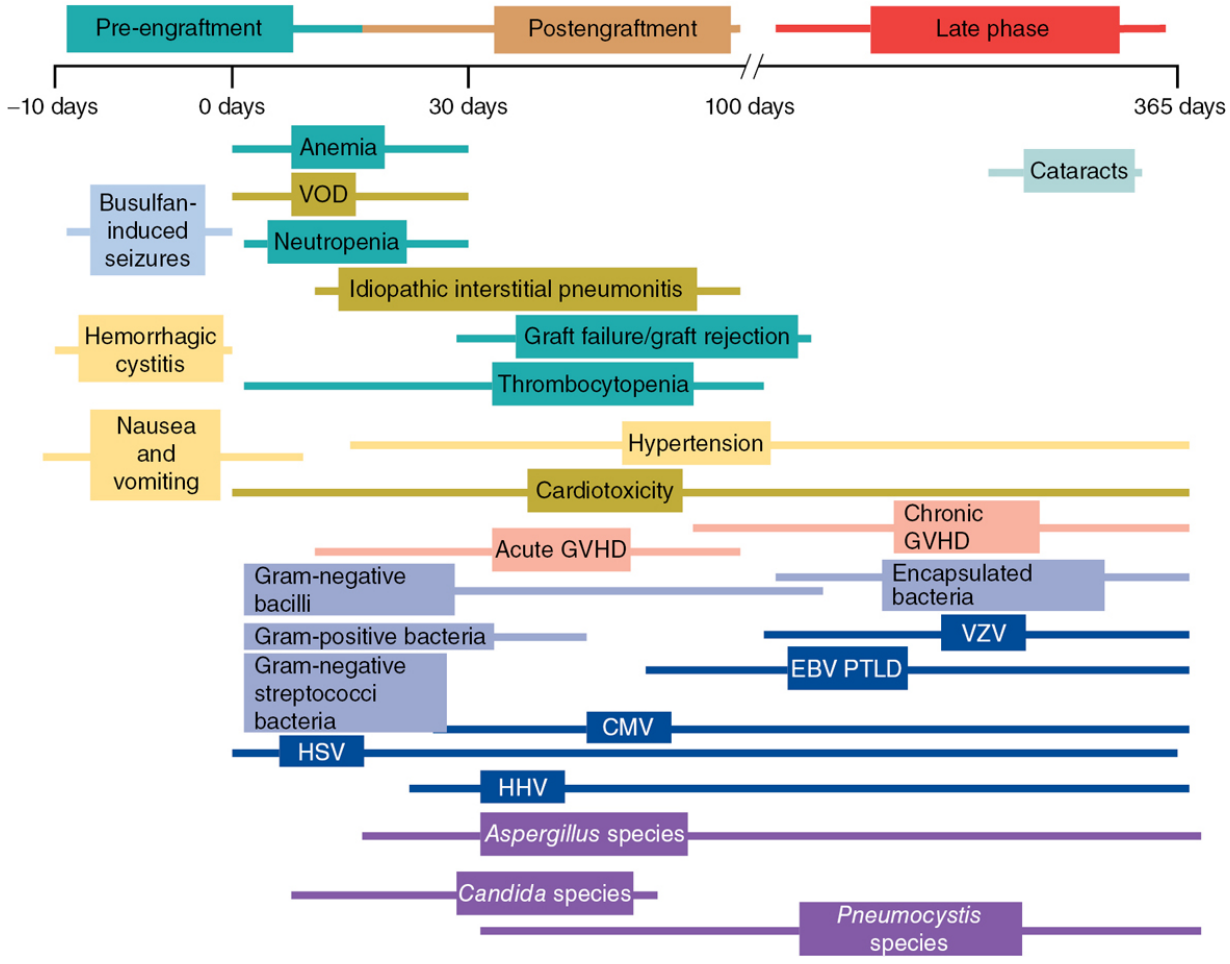

Figure 101-2 Complications after hematopoietic stem cell transplantation (HSCT) by time for patients undergoing

myeloablative allogeneic HSCT only. CMV, cytomegalovirus; EBV, Epstein–Barr virus; GVHD, graft-versus-host disease; HHV, human herpesvirus; HSV, herpes simplex virus; PTLD, posttransplantation lymphoproliferative disease; VOD, veno-occlusive disease; VZV, varicella-zoster virus.

Busulfan Seizures

Case 101-3, Question 2: In addition to her preparative regimen, the following supportive-care agents and monitoring parameters are prescribed for K.M.: on the day of admission (day −8), administer levetiracetam 500 mg PO twice daily from days −8 to −3. Busulfan pharmacokinetic blood sampling is to occur after dose 1 to a target busulfan area under the curve (AUC) >900 ng/mL. Begin normal saline hydration 3000 mL/m^2/day 4 hours before cyclophosphamide and continue for 24 hours after the last cyclophosphamide dose. Mesna is to be given concurrently with cyclophosphamide as 10% of the cyclophosphamide dose administered intravenously 30 minutes before starting the cyclophosphamide dose, then as 100% of cyclophosphamide dose administered as a continuous IV infusion for 24 hours after each dose of cyclophosphamide. Beginning on day −5, weigh patient twice daily, check fluid input and urinary output every 4 hours, and monitor urine for RBCs daily until 24 hours after the last cyclophosphamide dose. If urine output drops below 300 mL for 2 hours, administer an IV bolus of 250 mL normal saline and give furosemide 10 mg/m^2, not to exceed 20 mg IV. What is the rationale for these supportive-care therapies and monitoring parameters prescribed for K.M. as they relate to busulfan therapy?

Seizures occur in ~10% of patients receiving high-dose busulfan in HSCT preparative regimens. Busulfan is highly lipophilic and readily crosses the blood–brain barrier with an average cerebrospinal fluid/plasma ratio of 1 or higher. Seizures are probably a direct neurotoxic effect[91]; therefore, seizure prophylaxis is used. Many HSCT centers have moved from phenytoin to levetiracetam for seizure prophylaxis, although benzodiazepines (eg, lorazepam or clonazepam) also have been used.[92] Seizure prophylaxis is started at least 12 hours before the first busulfan dose and is usually discontinued 24 to 48 hours after administering the last busulfan

dose. Seizures can occur despite the use of seizure prophylaxis, but they usually do not result in permanent neurologic deficits.

Adaptive Dosing of Busulfan

Case 101-3, Question 3: What dosing strategies can be used to minimize busulfan toxicities?

Intravenous busulfan is commonly used in combination with cyclophosphamide as a preparative regimen before allogeneic HSCT for CML. The FDA-approved dose is 0.8 mg/kg IV every 6 hours for 16 doses, which is similar to the oral busulfan dose of 1 mg/kg, assuming a fraction absorbed of 90%.[93] Intravenous busulfan, at 0.8 mg/kg of actual body weight, produces an average AUC of 1200 μM/minute, within a wide range of 900 to 1500 μM/minute in 80% of patients.[94] Higher AUC values (>1500 μM/minute) have been associated with an increased risk of developing sinusoidal obstructive syndrome (SOS), formerly called veno-occlusive disease (SOS/VOD) of the liver; therefore, monitoring of busulfan AUC is warranted. Target AUCs are commonly between 900 and 1350 μM/minute after the first dose. This minimizes the risk of SOS/VOD and graft failure and minimizes the risk of disease recurrence[95] (see Case 101-3, Questions 7–9 for information on SOS/VOD).

To minimize adverse events from IV busulfan, an AUC is obtained with the first dose of busulfan to analyze K.M.'s exposure. Samples are drawn at the end of the 2-hour infusion, then 1, 2, and 4 hours after the first sample. Many centers are not capable of analyzing IV busulfan levels; therefore, prior arrangements must be made for timely analysis of these samples in order to adjust the dose after the second or third dose, if needed. K.M.'s AUC comes back 12 hours later at 1225 μM/minute and, therefore, her dose is not changed. Had the AUC been >1350 μM/minute, her dose could have been adjusted using the following formula:

$$\text{Adjusted dose (mg)} = \text{Actual dose (mg)} \times \text{Target AUC (}\mu\text{M/minute)/Actual AUC (}\mu\text{M/minute)}$$

(Eq. 101-1)

Hemorrhagic Cystitis

CASE 101-3, QUESTION 4: What is the rationale for these supportive-care therapies and monitoring parameters prescribed for K.M. as they relate to cyclophosphamide therapy?

In patients undergoing HSCT receiving cyclophosphamide, moderate-to-severe hemorrhagic cystitis occurs in 4% to 20% of patients receiving hydration alone.[96] Development of hemorrhagic cystitis is thought to be because of the bladder toxin acrolein, a metabolite of cyclophosphamide.[97] The chemoprotectant mesna donates free thiol groups that bind acrolein and reduce its toxicity. The American Society of Clinical Oncology (ASCO) guidelines on the use of chemotherapy and radiotherapy protectants recommends the use of mesna plus saline diuresis or forced saline diuresis to lower the incidence of urothelial toxicity with high-dose cyclophosphamide in the setting of HSCT.[98] It is important to note that hematuria or hemorrhagic cystitis can occur despite the use of any of these methods.

The optimal mesna dose with high-dose cyclophosphamide in preparation for myeloablative HSCT is unknown. A variety of different regimens have been used, including intermittent bolus dosing (mesna dose 20%–40% of cyclophosphamide dose, administered for up to five doses) or continuous infusion regimens (mesna dose 80%–160% of cyclophosphamide dose).[96,99,100] Mesna should be continued for 24 to 48 hours after the last cyclophosphamide dose, such that mesna is present within the bladder at the same time as the urotoxic metabolite acrolein. After IV administration of mesna, most of it (ie, 60%–100%) is excreted within the urine over the course of 4 hours.[101] Cyclophosphamide

has an average half-life of 7 hours after administration of 60 mg/kg,[102] and acrolein may be present within the urine for 24 to 48 hours after cyclophosphamide administration.[103]

Thus, K.M. is receiving hydration with normal saline and mesna, administered as a continuous infusion, to minimize her risk of hemorrhagic cystitis because of cyclophosphamide. K.M. should be monitored for any RBCs present in the urine, along with her urinary output, to allow for rapid intervention if hemorrhagic cystitis occurs.

Chemotherapy-Induced Gastrointestinal Effects

Case 101-3, Question 5: What other end-organ toxicities must be watched for? Should any medications be ordered for K.M. to prevent and treat the gastrointestinal (GI) effects associated with myeloablative therapy?

The high doses of chemotherapy in preparative regimens cause most patients to be nauseated and anorexic until day +10 to +15. Chemotherapy-induced nausea and vomiting in HSCT recipients can be because of highly emetogenic chemotherapy agents (see Chapter 22, Nausea and Vomiting), TBI administration, and poor control of nausea and vomiting prior to HSCT. Thus, patients such as K.M. who are undergoing a myeloablative HSCT should be given prophylaxis with a serotonin antagonist plus a corticosteroid.[105]

ASCO guidelines state that the use of the neurokinin receptor-1 antagonist, aprepitant, should be considered, although evidence to support its use in patients undergoing HSCT is lacking.[104] Because aprepitant is a moderate inhibitor of cytochrome P-450 3A4, it may theoretically interact with the preparative regimen, especially cyclophosphamide. Well-controlled studies evaluating its efficacy, along with its potential for causing drug interactions, are needed.[104] Some data suggest that the serotonin antagonist ondansetron may increase cyclophosphamide clearance in patients undergoing a myeloablative HSCT.[105,106] However, further work is needed to identify the clinical implications of this finding because, to date, cyclophosphamide concentrations have not been consistently

associated with clinical outcomes in patients undergoing a myeloablative HSCT.[19,93]

Most patients receiving a myeloablative preparative regimen may also experience mucositis because of its effects on rapidly dividing cells of the oral epithelium. The use of methotrexate as GVHD prophylaxis also contributes to mucositis.[107] Oral mucositis may also contribute to the development of nausea and anorexia.

In severe cases, parenteral opioid analgesics for pain relief[108] and total parenteral nutrition (TPN) may be needed. Because mucositis can be worsened by superinfection, good oral hygiene should be practiced. Soft toothbrushes should be used and replaced often.[109] Oral mucositis can be decreased with the use of recombinant human keratinocyte growth factor palifermin. The Multinational Association of Supportive Care in Cancer and International Society for Oral Oncology guidelines recommend palifermin to prevent mucositis for patients with hematologic malignancies receiving myeloablative chemotherapy and TBI with autologous HSCT. Palifermin 60 µg/kg/day is given for 3 days immediately prior to administering the preparative regimen and for 3 days after infusion of the hematopoietic stem cell graft (ie, days 0, +1, +2).[110] In these patients, palifermin lowered the incidence and average duration of clinically meaningful oral mucositis. The incidence of blood-borne infections and the use of parenteral opioids were also diminished in patients using palifermin.[110]

Myelosuppression and Growth Factor Use

Case 101-3, Question 6: An order is written to begin filgrastim on day +5 and to continue administration until the ANC has recovered to 500/µL for 2 consecutive days. Is this therapy appropriate for K.M.?

The use of hematopoietic growth factors after infusion of allogeneic PBPC is controversial and is not recommended by ASCO guidelines.[14] Administration of hematopoietic growth factors after allogeneic graft infusion decreases the duration of neutropenia but

has not been demonstrated to decrease cost, length of hospitalization, or antibiotic use. Hematopoietic growth factor administration may increase the incidence of severe GVHD and lower survival.[111] K.M. is receiving an allogeneic PBPC graft and thus, should not receive filgrastim.

Sinusoidal Obstructive Syndrome/ Veno-Occlusive Disease of the Liver

Case 101-3, Question 7: K.M.'s pretransplantation admission laboratory values are within normal limits. Her weight on admission is 176.37 pounds (80 kg). During the first 5 days after marrow infusion, K.M.'s weight begins to increase by ~0.5 kg/day, her inputs exceed her outputs by about 500 to 1000 mL/day, and she is mildly febrile with an axillary temperature of 100.40 °F (38 °C). Blood and urine cultures are all negative. On day +6, her weight is 187.39 pounds (85 kg). Laboratory values on day +7 are significant for the following:

Total bilirubin, 1.5 mg/dL
Aspartate aminotransferase (AST), 40 units/L
Alkaline phosphatase, 120 units/L

By day +10, K.M. endorses mid-epigastric, right upper quadrant pain, and a liver that is tender to palpation. During the next few days, K.M. begins to look icteric. Her liver function tests continue to rise slowly, until day +18 when they reach the following peak values:

Total bilirubin, 5 mg/dL
AST, 150 units/L
Alkaline phosphatase, 180 units/L

On day +18, K.M.'s weight is 198.41 pounds (90 kg). "Rule out SOS of the liver" is included on her problem list in the medical record. What is SOS?

SOS, formerly known as VOD, is a syndrome consisting of fluid retention, right upper quadrant pain, and hyperbilirubinemia. In severe cases, it results in renal failure, encephalopathy, multiorgan failure, and ultimately may result in death. The incidence of SOS/VOD varies depending on the definition used to diagnose the syndrome; however, it is most commonly associated with high-dose chemotherapy with HSCT. It has been reported to occur in 5% to

55% of patients undergoing myeloablative HSCT.[112,113] The major risk factor for the development of SOS/VOD is high-dose chemotherapy associated with myeloablative transplants. Preparative regimens, including busulfan, cyclophosphamide, and/or TBI >13.2 Gy, have been associated with higher SOS/VOD rates.[19,114] Patient-specific factors such as older age, impaired performance status, and advanced disease have also been reported to increase SOS/VOD risk.

Although the exact pathophysiology underlying the development of SOS/VOD is not fully understood, it is known that damage to the sinusoidal endothelial cells in the liver is the initial insult that initiates the process. Damage continues and leads to sloughing of the endothelial lining of the sinusoids ultimately resulting in embolism and obstruction of sinusoidal flow.[115] This obstruction of flow within the liver contributes to postsinusoidal portal hypertension and worsening liver dysfunction, usually manifested by increased bilirubin and ascites.

CLINICAL PRESENTATION AND DIAGNOSIS

Case 101-3, Question 8: What signs and symptoms in K.M. are consistent with a diagnosis of SOS/VOD?

The initial signs and symptoms of SOS/VOD can occur anytime within the first 15 to 30 days posttransplant. Insidious weight gain exceeding 5% of baseline may be one of the first manifestations of impending SOS/VOD, occurring in >90% of patients within 3 to 6 days after marrow infusion.[113] Weight gain is caused by sodium and water retention, as evidenced by decreased renal sodium excretion. New onset of transfusion refractory thrombocytopenia may also be an early sign of impending SOS/VOD. Hyperbilirubinemia, which also occurs in virtually all patients, follows the onset of weight gain and usually appears within 10 days after hematopoietic stem cell infusion. Other liver function test abnormalities usually occur after hyperbilirubinemia and include elevations in AST and alkaline

phosphatase. Ascites, right upper quadrant pain, and encephalopathy lag behind changes in liver function tests and develop within 10 to 15 days after infusion of HSCs.[113]

Although liver biopsy is the gold standard for the diagnosis of SOS/VOD, its use is limited because of the risk of bleeding during the procedure. Other noninvasive criteria have been developed to help diagnose SOS/VOD after HSCT. Two sets of clinical criteria call for an evaluation of hyperbilirubinemia, ascites/weight gain and right upper quadrant pain not attributable to other causes such as medications, aGVHD, or infection.[113,116] Along with these criteria, ultrasound may be useful in determining whether there is reversed hepatic venous flow and to confirm ascites and/or hepatomegaly.

Case 101-3, Question 9: What is the likelihood that K.M. will recover from her SOS/VOD? How should she be treated?

There is no standard treatment for SOS/VOD, although many patients with SOS/VOD (70%–85%) spontaneously recover. Preventive measures look to control patient risk factors, and pharmacologic prevention strategies have also been used. Patient-specific risk factors are often not reversible; however, selection of appropriate preparative regimens such as nonmyeloablative regimens, avoidance of concomitant hepatotoxic drugs, use of fractionated TBI, and the use of adaptive busulfan dosing may reduce risk. Preventive medications have also been investigated. The use of prophylactic heparin has shown varied results in clinical trials; therefore, its use is still controversial.[117] The data for the use of ursodeoxycholic acid are also inconclusive. However, some trials have shown a benefit in reducing the incidence of SOS/VOD with its use. According to one trial, patients who received ursodeoxycholic acid were shown to have decreased hepatotoxicity, less aGVHD, and better survival.[118]

Other treatments consist of supportive-care measures such as management of sodium and water balance and paracentesis, in severe cases, for ascites that is associated with pain and pulmonary

compromise.[107] Volume expanders such as albumin and colloids may be used to maintain intravascular volume, spironolactone may be used to minimize extravascular fluid accumulation, and protein restriction and lactulose may be used if encephalopathy develops. Unfortunately, improved outcomes with these measures have not been confirmed. In patients with severe SOS/VOD and multiorgan failure, available treatment options are limited. Thrombolytic therapy with recombinant human tissue plasminogen activator and heparin have had mixed results in terms of efficacy and can cause fatal intracerebral or pulmonary bleeding.[107] Defibrotide has shown promising results in the treatment of SOS/VOD.[119–121] Defibrotide, a ribonucleotide, has antithrombotic, anti-ischemic, and thrombolytic activity without producing significant systemic anticoagulation.

A phase-3 trial looked at the efficacy of defibrotide in patients with established SOS/VOD and multiorgan failure. Patients (n = 102) were given defibrotide at 25 mg/kg/day and compared to historical controls. The primary end point was survival at day +100 after HSCT. Those receiving defibrotide had a survival rate of 38.2% at day +100 versus 25% in the control group.[121]

Because K.M. does not meet the criteria for severe SOS/VOD, she should be managed conservatively with fluid restriction and spironolactone for fluid diuresis. Her signs and symptoms should resolve during the next 2 weeks. Because she has mild SOS/VOD, she is likely to recover completely without sequelae.

Graft Rejection

CASE 101-4

Question 1: E.R. is a 65-year-old female diagnosed with myelodysplastic syndrome. Past medical history is significant for type I diabetes and renal dysfunction. After her initial diagnosis, a search for a completely HLA-MUD was conducted. A donor was found in the National Marrow Donor Registry, and E.R. will receive a nonmyeloablative allogeneic HSCT using BM from an unrelated male donor. E.R.'s preparative regimen is as follows: fludarabine 30 mg/m^2/day on days −4, −3, and −2 and 2 Gy TBI on the day of marrow infusion with

posttransplant cyclosporine and mycophenolate mofetil. It is now day +28 and E.R.'s CBC shows the following:

WBC count, 500 cells/μL
Differential, no granulocytes or monocytes detected
Platelets, 100,000/μL
Hematocrit (HSCT), 30%
Donor T-cell chimerism, >5%

What is E.R. experiencing and how should she be treated?

Reduced-intensity regimens typically consist of fludarabine in combination with an alkylating agent or low-dose TBI (**Fig. 101-3**). With the nonmyeloablative fludarabine/TBI regimen, there is minimal neutropenia, thrombocytopenia, and other nonhematologic toxicities.[2] Engraftment is usually evident within the first 30 days in patients receiving a nonmyeloablative preparative regimen; however, rejection can occur after initial engraftment.[122] Mixed chimerism, a state where both host and donor cells coexist, generally develops after nonmyeloablative HSCT. E.R. has low donor T-cell chimerism on day +28, placing her at high risk of graft rejection.

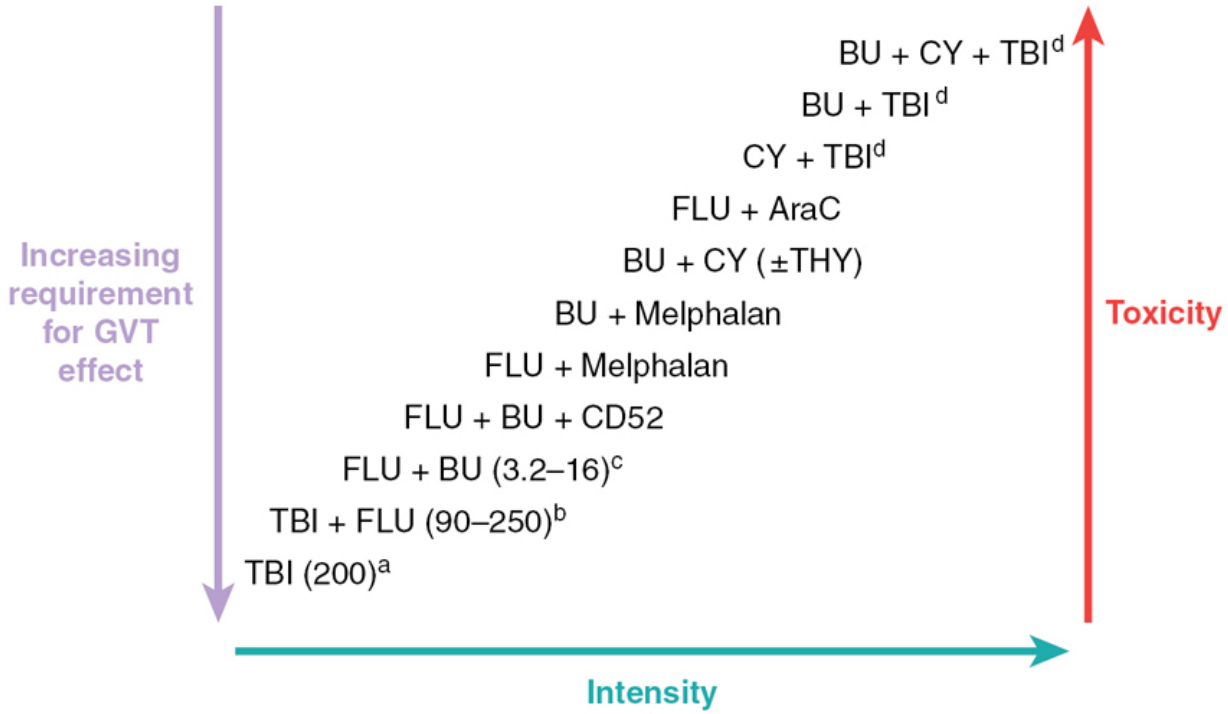

Figure 101-3 Partial spectrum of preparative regimens of various intensities, their impact on toxicity, and their dependence on graft-versus-tumor (GVT) effects for success of hematopoietic stem cell transplantation. AraC, cytarabine; BU, busulfan; CD52, anti-CD52 antibody (alemtuzumab); CY, cyclophosphamide; FLU, fludarabine; TBI, total body irradiation; THY, thymoglobulin. [a]200 cGy; [b]90 to 250 mg/m2; [d]3.2 to 16 mg/kg; [d]TBI >1200 cGy. (Adapted by permission from Nature: Deeg HJ, Maris MB, Scott BL, Warren EH. Optimization of allogeneic transplant conditioning: not the time for dogma. *Leukemia*. 2006;20(10):1701–1705. © 2006 Springer Nature.)

Graft rejection occurs particularly after nonmyeloablative allogeneic HSCT. A delicate balance exists between host and donor effector cells. This is established with myelosuppressive chemotherapy and immunosuppressants to decrease the risk of excessive host-versus-graft effects that could lead to graft rejection. The incidence of graft rejection is higher in patients with aplastic anemia and in patients undergoing HSCT with histoincompatible marrow or T-cell–depleted marrow. There are limited therapeutic options for the treatment of graft rejection. A second HSCT is the most definitive therapy, assuming donor cells are available, although the toxicities are formidable.[123] In patients receiving myeloablative allogeneic HSCT, graft rejection is best managed with immunosuppressants such as ATG. In patients receiving a reduced-intensity regimen, graft rejection may require a second HSCT.

E.R. received nonmyeloablative conditioning, and thus, she should have mixed chimerism posttransplant; however, she has <5% donor T cells. Current research is focusing on quantitative chimerism monitoring, specifically evaluating the percent donor chimerism, which may be used as a tool with which to base clinical interventions.[82] Donor chimerism is evaluated in different cell types (eg, T cells, NK cells, granulocytes), although the cell type most predictive of outcome is not known. The changes in the percent donor chimerism over time posttransplant, termed “engraftment kinetics,” are influenced by several factors such as type of HSCT conditioning, stem cell source, and intensity of postgrafting

immunosuppression.[82,124] A balance between the recipient's and donor's cells is needed to maximize the GVT effect, which lowers the risk of relapse while minimizing the risk of GVHD.[82,124] Based on E.R.'s state of chimerism, she will not benefit from the GVT effect because of the lack of the donor's cytotoxic T lymphocytes that suppress the recipient's malignancy.

E.R. is at high risk of graft rejection and therefore may not benefit from the transplant. A trial of discontinuing cyclosporine and mycophenolate mofetil, in an attempt to shift the balance toward donor graft growth and away from recipient T-cell growth, is an option. E.R.'s T-cell chimerism should be monitored periodically, and hematopoietic function should be monitored with daily CBC and a BM biopsy as clinically indicated.

GRAFT-VERSUS-HOST DISEASE

GVHD is caused by activation of donor lymphocytes, leading to immune-mediated damage to the recipient. Histocompatibility differences between donor and recipient necessitate posttransplantation immunosuppression after allogeneic HSCT because considerable morbidity and mortality are associated with graft rejection and GVHD. Therefore, immunosuppression or GVHD prophylaxis is used after allogeneic HSCT. However, because allogeneic transplantation offers the potential for a GVT effect in which immune effector cells from the donor recognize and eliminate residual tumor in the recipient, research is focusing on immune suppression manipulations that allow sufficient GVT effects while not increasing the risk of graft rejection and GVHD.[125]

GVHD is the most important complication of allogeneic HSCT and limits the use of this life-saving treatment in patients without histocompatible donors.[2,126] GVHD can occur after allogeneic HSCT, regardless of the preparative regimen used. The pathophysiology of GVHD is not completely understood, but the current view of its development is described by a three-step process, including (a) the

preparative regimen causing tissue damage and release of inflammatory cytokines into the circulation; (b) recipient and donor antigen-presenting cells and inflammatory cytokines triggering activation of donor-derived T cells; and (c) activated donor T cells mediating cytotoxicity through a variety of mechanisms, which leads to tissue damage characteristics of aGVHD.[127]

GVHD has traditionally been divided into two forms (ie, acute or chronic) based on time points and clinical manifestations. Acute GVHD, defined as occurring during the first 100 days posttransplant, damages the skin, GI tract, and liver.[2] In contrast, cGVHD may affect almost any organ system, closely resembles several autoimmune diseases, and occurs after day 100. With the introduction of nonmyeloablative HSCT, the time course of GVHD has shifted and a late-onset aGVHD occurring after day 100 is possible; however, in these individuals, both aGVHD and cGVHD symptoms may be present. As such, consensus criteria developed by the National Institutes of Health have classified GVHD based on clinical manifestations and not time after HSCT.[128]

The majority of the data regarding the prevention and treatment of GVHD have been obtained after myeloablative preparative regimens. Therefore, the subsequent section refers only to trials conducted in recipients of a myeloablative allogeneic HSCT.

Acute Graft-Versus-Host Disease

RISK FACTORS

CASE 101-5

Question 1: M.P., a 22-year-old, 154.32 pounds (70 kg) male, undergoes a one-antigen mismatched allogeneic HSCT from his sister for the diagnosis of Philadelphia chromosome-positive (Ph^+) AML. After a myeloablative preparative regimen of CY/TBI, the following immunosuppressive regimen is ordered: cyclosporine 2.5 mg/kg every 12 hours from day −3 until tolerating oral medications, then switch to cyclosporine 4 mg/kg PO every 12 hours until day +50. Methotrexate 15 mg/m^2 IV on day +1, then 10 mg/m^2 on days +3, +6, and +11.

What factors are associated with an increased risk of aGVHD?

The single most important factor associated with the development of GVHD is the degree of histocompatibility between donor and recipient.[2] Clinically relevant grade II–IV aGVHD occurs in 20% to 50% of HLA-matched sibling grafts and 50% to 80% of HLA-mismatched sibling or HLA-identical unrelated donors.[129] The onset of aGVHD is earlier and severity is increased in mismatched grafts relative to matched grafts, and also in MUDs relative to matched sibling donors.[41,130] Other factors that increase the risk of experiencing aGVHD include increasing recipient (and possibly donor) age, greater intensity of the preparative regimen, use of PBPC rather than BM, and donor/recipient sex mismatch.[127] Umbilical cord transplants have a lower risk of aGVHD.[131–133]

M.P. is receiving allogeneic BM from a female sibling donor that is mismatched at one HLA antigen. These two factors increase his risk of exhibiting aGVHD. Therefore, good immunosuppressive therapy is critical in preventing its development.

CLINICAL PRESENTATION

Case 101-5, Question 2: On day +14, the time at which engraftment has occurred, M.P. is noted to have a diffuse maculopapular rash on his arms, hands, and front trunk. He does not have diarrhea, and his liver function tests are within normal limits. At the onset of his rash, M.P.'s empiric antibiotics are changed from cefepime to meropenem. Despite the change in antibiotics, M.P.'s rash persists. How is M.P.'s presentation consistent with aGVHD?

aGVHD is usually not evident until the time of engraftment, when donor lymphoid elements begin to proliferate. The primary targets of immune-mediated destruction of host tissue by donor lymphocytes in aGVHD are the skin followed by the GI tract (diarrhea) and the liver.[129,134] aGVHD of the skin, the most common site of aGVHD, usually manifests as a diffuse maculopapular, pruritic rash that starts on the palms of the hands, soles of the feet, or the face. In more

severe cases, skin aGVHD can progress to a generalized total body erythroderma, bullous formation, and skin desquamation.

The earliest symptoms of aGVHD of the GI tract are usually loss of appetite followed by nausea and vomiting.[107] Abdominal pain and watery or bloody diarrhea also occur, which can result in electrolyte abnormalities, dehydration, or ileus in severe cases. Liver GVHD usually follows skin and/or GI GVHD. Clinical symptoms of liver GVHD include a gradual rise in total bilirubin, alkaline phosphatase, and hepatic transaminases.[107]

aGVHD must be distinguished accurately from other causes of skin, liver, or GI toxicity in the HSCT patient. For example, a maculopapular rash, which may occur as a manifestation of an allergic reaction to antibiotics, usually begins on the trunk or upper extremities and is rarely present on the palms of the hands or soles of the feet. Diarrhea can be caused by chemotherapy, radiation, infection, or antibiotic therapy.[107] However, diarrhea caused by the preparative regimen is rarely bloody and usually resolves within 3 to 7 days after discontinuation of drugs and radiation. Diarrhea caused by infectious agents such as *Clostridioides difficile* or cytomegalovirus (CMV) should be distinguished from GVHD. Liver GVHD must be distinguished primarily from SOS/VOD and, to a lesser extent, hepatitis induced by drugs, blood products, or parenteral nutrition. Although liver function test abnormalities between these syndromes are similar, liver GVHD is rarely associated with insidious weight gain or right upper quadrant pain.[107] A tissue biopsy of the affected organ in conjunction with clinical evidence is the only way to definitively diagnose aGVHD, although biopsy of the gut or liver is rarely done because of the increased risks associated with thrombocytopenia early in the posttransplant phase. aGVHD is associated with characteristic histologic changes to affected organs. A staging system based on clinical criteria is used to grade aGVHD. The severity of organ involvement is determined first (**Table 101-6**), and then an overall grade is established based on number and extent of involved organs (**Table 101-7**).

Table 101-6
Modified Glucksberg Grading of Acute Graft-Versus-Host Disease

Organ Stage	Skin	Liver	Gut
Glucksberg Grading			
I—Mild	Stages 1–2	None	None
II—Moderate	Stage 3 or	Stage 1 or	Stage 1
III—Severe		Stages 2–3 or	Stages 2–4
IV—Life-threatening	Stage 4 or	Stage 4	—
IBMTR Grading			
A—Mild	Stage 1	None	None
B—Moderate	Stage 2	Stage 1 or 2	Stage 1 or 2
C—Severe	Stage 3	Stage 3	Stage 3
D—Life-threatening	Stage 4	Stage 4	Stage 4

M.P. developed a rash at the time of engraftment that could have been consistent with either an antibiotic-induced rash or aGVHD. Although it was appropriate to change antibiotics, the fact that M.P.'s rash did not improve is suggestive of aGVHD. M.P.'s rash is present on 36% of his body, but because there are no signs of GI or liver involvement at this time, M.P. is likely to have grade I aGVHD (Tables 101-6 and 101-7).

IMMUNOSUPPRESSIVE PROPHYLAXIS

Case 101-5, Question 3: Why did M.P. receive prophylactic immunosuppressive therapy with cyclosporine and methotrexate?

GVHD is a leading cause of morbidity and mortality after allogeneic HSCT. Without immunosuppression, serious aGVHD would occur in almost every allogeneic HSCT recipient.[2] The most common method used to minimize GVHD risk is to administer prophylactic immunosuppressive therapies, and most patients receive multidrug GVHD prophylaxis.

Historically, aGVHD was prevented with single-drug therapy using ATG, cyclophosphamide, methotrexate, or cyclosporine.[135–137] ATG binds nonspecifically to mononuclear cells and depletes hematopoietic progenitor cells in addition to lymphocytes. Consequently, ATG is generally avoided as a prophylactic agent because of the risk of graft failure.[135] The risk of GVHD is greatly reduced by two-drug combination immunosuppression (**Table 101-8**). Although the most widely published regimen is short-course methotrexate plus cyclosporine,[137] there is no consensus with regard to the most effective regimen. Several randomized clinical trials have

compared tacrolimus and short-course methotrexate with cyclosporine plus short-course methotrexate in patients undergoing allogeneic HSCT using HLA-matched siblings[138,139] and unrelated donors.[88] Recipients of matched sibling grafts treated with tacrolimus had a lower incidence of grade II to IV aGVHD but a similar incidence of cGVHD.[138] Overall survival was lower in the tacrolimus group as a result of more toxic deaths in patients with advanced-stage disease; however, a higher number of patients with advanced-stage disease in the tacrolimus/methotrexate group make the results of this trial somewhat difficult to interpret.[138]

Table 101-8

Combination Immunosuppression Regimens for Prophylaxis of Acute Graft-Versus-Host Disease in Myeloablative Transplant

Drug	Dosing Examples
Cyclosporine/short-term methotrexate	1.5 mg/kg IV or 4 mg/kg (Neoral) PO every 12 hours, days −1 to +50, then taper 5% per week and discontinue by day +180
	Methotrexate 10 mg/m^2 IV, days +3, +6, +11
Tacrolimus/short term	Tacrolimus 0.03 mg/kg/day continuous IV infusion or 0.12 mg/kg/day PO bid
Methotrexate[136]	Methotrexate 15 mg/m^2 IV day +1; 10 mg/m^2 IV, days +3, +6, +11
Cyclosporine/methotrexate/prednisone	Cyclosporine 5 mg/kg/day IV continuous infusion, days –2 to +3, then 3–3.75 mg/kg IV until day +35; then 7 mg/kg/day (Neoral) PO, dose adjusted to cyclosporine concentrations (via radioimmunoassay) of 200–400 ng/mL. Taper by 20% every 2 weeks; then discontinue by day +180
	Methotrexate 15 mg/m^2 IV day +1; 10 mg/m^2 IV days +3, +6

Drug	Dosing Examples
	Methylprednisolone 0.5 mg/kg/day IV day +7 until day +14; then 1 mg/kg/day IV until day +28; then prednisone 0.8 mg/kg/day PO until day +42; then taper slowly and discontinue by day +180

bid, twice a day; IV, intravenous; PO, orally.

Source: Deeg HJ, Storb R, Thomas ED, et al. Cyclosporine as prophylaxis for graft-versus-host disease: a randomized study in patients undergoing marrow transplantation for acute nonlymphoblastic leukemia. *Blood*. 1985;65:1325–1334.

Subsequently, the International Blood and Marrow Transplant Registry conducted a matched control study, which suggested that the survival difference between the two arms of tacrolimus plus short-course methotrexate and cyclosporine plus short-course methotrexate was in fact because of the imbalance in the underlying risk factors.[139] In patients receiving HLA-matched or slightly mismatched-unrelated grafts, those given tacrolimus had a lower incidence of grade II to IV aGVHD, a similar incidence of cGVHD, and similar disease-free and overall survival rates.[88] Both regimens are currently used in allogeneic HSCT after myeloablative preparative regimens.

More recently, the use of mycophenolate mofetil has been studied in allogeneic transplants with myeloablative conditioning used in combination with cyclosporine. It appears to have a similar incidence of aGVHD and 100-day survival as methotrexate/cyclosporine, yet significantly less severe mucositis and more rapid neutrophil engraftment than the methotrexate/cyclosporine arm.[140,141] Mycophenolate mofetil is now commonly used in clinical practice in combination with cyclosporine or tacrolimus.

M.P. received aGVHD prophylaxis with a two-drug regimen of short-course methotrexate and cyclosporine, the most common regimen for myeloablative allogeneic conditioning regimens. Using two drugs with different mechanisms of immunosuppression, one blocking the activation of T cells (cyclosporine) and the other (methotrexate) blocking the division and clonal expansion of

activated T cells, is more effective in decreasing the likelihood of GVHD than one of these agents alone.

Case 101-5, Question 4: What principles are used in dosing medications used for aGVHD prophylaxis?

Although the various combination immunosuppressive regimens vary slightly by drug, dose, and combination, several guidelines are consistent throughout all regimens. First, methotrexate used for prophylaxis of aGVHD is withheld or given in reduced doses if mucositis is severe or the patient experiences excessive fluid retention.[137,142] Fluid retention sites act as a depot for methotrexate accumulation, increasing duration of exposure. Methotrexate for GVHD prophylaxis can delay engraftment, increase the incidence and severity of mucositis, and cause liver function test elevations. The methotrexate dose is reduced in the setting of renal or liver impairment.[137,143]

The calcineurin inhibitors (ie, cyclosporine, tacrolimus) should be initiated before or immediately after donor cell infusion (day −3 to 0) when used for GVHD prophylaxis. This schedule is recommended because of the known mechanism of action of these agents, which entails blocking the proliferation of cytotoxic T cells by inhibiting the production of helper T-cell–derived interleukin-2 (IL-2). Administering calcineurin inhibitor before the donor cell infusion allows inhibition of IL-2 secretion to occur before a rejection response has been initiated.

Empiric dose adjustments may be required when patients are receiving concomitant medications (eg, voriconazole) that affect cytochrome CYP3A4 or P-glycoprotein, which are involved in the metabolism and transport of the calcineurin inhibitors. Thus, careful monitoring for drug interactions with the calcineurin inhibitors is warranted.[144] Although the calcineurin inhibitors do not contribute to myelosuppression, common adverse effects to these agents include electrolyte abnormalities, neurotoxicity, hypertension, and/or nephrotoxicity.[91]

Tapering schedules for GVHD prophylaxis vary widely among institutions. The general goal is to keep calcineurin inhibitor doses stable until day +50 and then slowly taper with the intent of discontinuing all immunosuppressive agents by 6 months after HSCT. By this time, immunologic tolerance has developed, and patients no longer require immunosuppressive therapy. This can only be accomplished if the patient is not experiencing GVHD.

ADAPTIVE DOSING OF CALCINEURIN INHIBITORS

CASE 101-5, QUESTION 5: On day +18, a cyclosporine concentration is measured right before the morning dose (trough) and is reported as 392 ng/mL. Why are cyclosporine concentrations being obtained for M.P.?

The role of pharmacokinetic monitoring of the calcineurin inhibitors in patients undergoing HSCT is not well defined but is commonly performed because of the established pharmacodynamic associations within solid-organ transplant recipients. It is standard practice for HSCT centers to adjust cyclosporine or tacrolimus doses based on trough blood concentrations.[145] An association between cyclosporine concentrations and aGVHD was not found in early studies; however, other studies have suggested that cyclosporine trough concentrations for 12-hour dosing of 200 to 400 ng/mL in adult patients minimize the risk of aGVHD and the risk of cyclosporine-induced nephrotoxicity.[146–148] For continuously infused cyclosporine, higher target blood concentrations of 300 to 500 ng/mL have been required to prevent GVHD in order to provide an equivalent AUC of exposure to intermittent dosing.[149,150] It is important to note that cyclosporine-induced nephrotoxicity may occur despite low or normal concentrations of cyclosporine and may be a consequence of other drug- or disease-related factors known to influence the development of nephrotoxicity. Additionally, recent studies suggest that trough concentrations do not correlate well with exposure to cyclosporine and that a peak level is better correlated to the $AUC_{(0–12).}$ A peak concentration of >800 ng/mL may be required

to prevent GVHD. Despite this, the data are limited and the routine use of peaks for therapeutic drug monitoring is not recommended.[151] Desired tacrolimus trough concentrations are 5 to 15 ng/mL. Tacrolimus concentrations >20 ng/mL have been associated with increased risk of toxicity, primarily nephrotoxicity.[145,152] Adjustments in tacrolimus dosing for increased SCr should be made in a manner similar to that described for cyclosporine.

It is reasonable to adjust M.P.'s doses to maintain cyclosporine trough concentrations between 200 and 400 ng/mL, as in all patients undergoing allogeneic HSCT with a myeloablative preparative regimen. Recommendations for dose adjustments should be based on cyclosporine concentrations and SCr level. No standard dosage adjustment schedule exists, but most centers adopt their own standardized approach. M.P. has a normal SCr, and his cyclosporine trough is 392 ng/mL. Therefore, his cyclosporine dose should be maintained, and the trough repeated in a few days. It may be repeated sooner if an interacting drug is added or discontinued, or if there are toxicity concerns.

TREATMENT OF ESTABLISHED ACUTE GRAFT-VERSUS-HOST DISEASE

Case 101-5, Question 6: In the third week posttransplant, M.P. experiences a pruritic rash on his shoulders and neck that spreads to the palms of his hands and looks like a sunburn. On day +19, the suspicion of acute skin GVHD is confirmed by biopsy. On the same day, M.P. develops diarrhea (1000 mL over 24 hours) and is noted to have bilirubin of 2.8 mg/dL. He is started on methylprednisolone 1 mg/kg IV every 12 hours. What is the rationale for methylprednisolone therapy in M.P.?

Preventing the development of aGVHD is the most effective way to treat this HSCT complication. In patients who develop aGVHD, first-line treatment is a corticosteroid added to their current immune suppression regimen.[127] For this reason, aGVHD and its treatment cause profound immunodeficiency.[2,153] The combination of aGVHD

and infectious complications is the leading cause of mortality for patients undergoing allogeneic HSCT.

The route of corticosteroid administration is determined by the severity of the aGVHD. Those patients with only skin involvement of <50% of their body surface area may be treated with topical steroid creams, whereas involvement of other organs, or stage 3 or 4 skin disease, requires systemic corticosteroids. A complete response occurs in up to 25% to 40% of patients, with a lower likelihood of response in more severe cases of aGVHD.[127,153] Patients with mild-to-moderate (grades I–III) aGVHD who respond to initial therapy have a significantly better survival advantage than patients with severe aGVHD who do not respond to initial therapy. Patients who do not respond to corticosteroid therapy or have ongoing severe GVHD usually die from a combination of GVHD and infectious complications.[154]

Corticosteroids used in the treatment of aGVHD are generally tapered based on response. There is no consensus on the optimal method for tapering the corticosteroids,[153] and the tapering rate depends on the patient. Patients who experience aGVHD or who experience flares of existing GVHD during a tapering trial will have their dosages increased or tapered more slowly as tolerated.

Because M.P. had objective evidence of established aGVHD, he was given systemic IV corticosteroids. This was appropriate because single-agent corticosteroids are considered the therapy of choice for established aGVHD.[155] Corticosteroids indirectly halt the progression of immune-mediated destruction of host tissues by blocking macrophage-derived IL-1 secretion. IL-1 is a primary stimulus for helper T-cell–induced secretion of IL-2, which in turn is responsible for stimulating proliferation of cytotoxic T lymphocytes. The recommended dosage of methylprednisolone for the treatment of established aGVHD is 1 to 2 mg/kg/day, given intravenously or orally in divided doses, followed by a tapering schedule that is determined by response.[154,155] Trials that compared higher doses of corticosteroids (ie, 10 mg/kg/day) to 2 mg/kg/day as initial treatment of aGVHD showed no advantage.[156] Monitoring for rash, diarrhea, and bilirubin levels to assess aGVHD response should occur daily.[127]

M.P. was receiving cyclosporine for GVHD prophylaxis at the time the aGVHD developed. Although the cyclosporine was not effective in preventing the aGVHD, it is typical for patients to remain on their prophylactic immune suppressants.

A significant portion of patients do not respond to corticosteroids, and they are said to have steroid-refractory GVHD.[127] If aGVHD symptoms worsen during 3 days of treatment and if the skin does not improve by 5 days, it is unlikely that a response will be achieved in a timely manner, and secondary therapy should be considered.[127] Patients with steroid-refractory aGVHD have a poorer prognosis. A variety of medications are being studied for "salvage" or secondary therapy. The salvage therapy depends on the organs affected. For example, phototherapy is used as salvage therapy for skin GVHD, and nonabsorbable corticosteroids are used for GI GVHD. Other options for salvage therapy include ATG, denileukin diftitox, and TNF-α blockers (eg, infliximab, etanercept).[127,157] The most effective dose, timing, or combination of these salvage therapies is still unknown.

M.P. should be evaluated for response to methylprednisolone after 4 to 7 days. If his aGVHD has improved or stabilized, he should be continued on therapy at this dose for a total of 14 days. If M.P. responds to therapy, his methylprednisolone dose should be tapered slowly over a minimum of 1 month, and he should be monitored for any evidence of recurrent GVHD. If the GVHD flares during his steroid taper as evidenced by worsening skin reactions, increased bilirubin, or increased diarrhea volume, the dose should be increased again until his disease is stable; the subsequent taper should be initiated at a slower rate. If M.P. fails to respond to first-line therapy with methylprednisolone, he should receive salvage therapy.

Chronic Graft-Versus-Host Disease

CLINICAL PRESENTATION

Case 101-5, Question 7: M.P. was successfully treated for his aGVHD, is no longer taking corticosteroids, and is currently tapering off his cyclosporine. On day +200, M.P. comes to clinic for follow-up after a 2-week vacation in Florida. On examination, M.P. is found to have a mild skin rash on his arms and legs, hyperpigmentation of the tissue surrounding the eyes, and white plaque-like lesions in his mouth. He also endorses dry eyes. Laboratory tests reveal an increased alkaline phosphatase and total bilirubin concentration. What is the most likely cause of M.P.'s findings?

cGVHD, the most common late complication of allogeneic HSCT, occurs in 20% to 70% of patients surviving >100 days.[158] cGVHD is a major cause of nonrelapse morbidity and mortality.[2] Risk factors for cGVHD include recipient, donor, and transplant factors. Nonmodifiable recipient risk factors include older age, certain diagnoses (eg, CML), and lack of an HLA-matched donor. Modifiable factors that may lower the risk of cGVHD include selecting a younger donor, avoiding a multiparous female donor, using umbilical cord blood or a BM graft rather than PBPC, and limiting the CD34+ and T-cell dose infused.[156] Development of aGVHD is a major predictor of cGVHD; 70% to 80% of those with grade II to IV aGVHD go on to develop cGVHD.[156]

cGVHD is not a continuation of aGVHD. Traditionally, the boundary between the two was based on time, but now they are classified based on different clinical symptoms.[158] Signs and symptoms of cGVHD in various organ systems are listed in **Table 101-9**.

Table 101-9
Selected Signs and Symptoms of Chronic Graft-Versus-Host Disease

Affected Organ	Diagnostic	Distinctive	Other Features[a]	Seen With Both Acute and Chronic GVHD
Eyes		New-onset dry, gritty, or painful eyes[b]	Photophobia	
		Cicatricial conjunctivitis Keratoconjunctivitis sicca[b]	Periorbital hyperpigmentation	
		Confluent areas of punctuate keratopathy, tear formation, dry eyes, burning, photophobia	Erythema of the eyelids with edema	
Gastrointestinal tract	Esophageal web		Pancreatic insufficiency	Anorexia
	Stricture or stenosis in the upper- to mid-third of the esophagus[c]			Nausea Vomiting Diarrhea Weight loss
Failure to thrive (infants and children)				
Liver				Total bilirubin, alkaline phosphatase >2 × upper limit of normal[c]
Lung	Bronchiolitis obliterans diagnosed with lung biopsy	Bronchiolitis obliterans diagnosed with pulmonary function tests and radiology[b]		Bronchiolitis obliterans organizing pneumonia
Skin	Poikiloderma	Depigmentation	Seat impairment ichthyosis	Erythema
	Lichen planus-like features		Keratosis pilaris	Maculopapular rash Pruritus
	Sclerotic features		Hypopigmentation	
	Morphea-like features		Hyperpigmentation	
		Lichen sclerosus–like features		

Signs and symptoms for hematopoietic and immune differences, as well as for nails; scalp and body hair; mouth; genitalia; muscles, fascia, and joints; and other organs, are also described by Filipovich et al.[128]

GVHD, graft-versus-host disease.

[a]Part of chronic GVHD symptomatology if the diagnosis is confirmed.

[b]Diagnosis of chronic GVHD requires biopsy or radiology confirmation (or Schirmer test for eyes).

[c]Infection, drug effects, malignancy, or other causes must be excluded.

A consensus guideline for the diagnosis and scoring of cGVHD has been published.[128] The diagnosis of cGVHD requires (a) being distinct from aGVHD, (b) having at least one diagnostic clinical sign of cGVHD or at least one distinctive manifestation confirmed by pertinent biopsy or other relevant tests, and (c) exclusion of other possible diagnoses. The clinical scoring system uses a numerical value of 0 to 3, with more severe symptoms having a higher number. A global score is calculated by including the number of organs involved and the severity within each affected organ. The global score reflects the expected effect of cGVHD on the patient's

performance status and can be used to evaluate whether treatment with systemic immunosuppression is required. The grading and prognosis of cGVHD can define and predict high-risk patient groups.[159]

The signs and symptoms of cGVHD in M.P. include a rash in sun-exposed areas of the skin, hyperpigmentation of tissues surrounding his eyes, white plaque-like lesions in the mouth, dry mucous membranes, and increased alkaline phosphatase and total bilirubin levels. These symptoms appeared after a period of complete resolution of aGVHD and during a taper of the cyclosporine. Thus, M.P. has moderate-involvement, quiescent cGVHD.[128]

PHARMACOLOGIC MANAGEMENT

Case 101-5, Question 8: M.P. is started on prednisone 1 mg/kg PO daily for the treatment of his cGVHD. His cyclosporine taper is stopped, and the dosage is raised to therapeutic concentrations. Is this therapy rational? What other agents are available to treat cGVHD?

There is no specific prophylactic therapy for cGVHD, and the optimal treatment remains controversial. The mainstay of therapy for cGVHD is long-term immunosuppressive therapy. Survival for patients with cGVHD is improved by extended corticosteroid therapy, although there are multiple long-term adverse effects associated with the corticosteroids.[158,160] A typical regimen is prednisone 1 mg/kg/day, administered orally in divided doses for 14 days and then converted slowly to alternate-day therapy by increasing the “on-day” and decreasing the “off-day” dose until a total of 1 mg/kg/day on alternate days is administered.[160] Alternate-day therapy is preferred to minimize adrenocortical suppression. Once therapy is initiated, 1 to 2 months may pass before an improvement in clinical symptoms is noted. Therapy is usually continued for 9 to 12 months and then slowly tapered after signs and symptoms of cGVHD have resolved. The median duration of treatment has been reported to be 23 months.[161] If cGVHD worsens during the tapering or after discontinuation of prednisone, immunosuppressive therapy is

restarted. Other potential approaches for patients with refractory cGVHD include mycophenolate mofetil, daclizumab, sirolimus, pentostatin, and extracorporeal photophoresis.[160]

When immunosuppressive therapy is administered for long periods, the patient must be monitored closely for chronic toxicity. Cushingoid effects, aseptic necrosis of the joints, and diabetes can develop with long-term corticosteroid use. Other severe complications include a high incidence of infection with encapsulated organisms and atypical pathogens such as *Pneumocystis jirovecii* pneumonia, CMV, and herpes zoster.

It is reasonable to start M.P. on single-agent prednisone for cGVHD treatment at 1 mg/kg daily for 2 weeks and then convert to every other day as described.

ADJUVANT THERAPIES

Case 101-5, Question 9: While on prednisone for his cGVHD, what supportive therapies should also be instituted in M.P.?

Patients who are being treated for cGVHD should receive trimethoprim–sulfamethoxazole for prophylaxis of *P. jirovecii* and encapsulated organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. Ensuring optimal prophylactic antibiotics in patients with cGVHD is critical because infection is the primary cause of death during treatment.[161] Artificial tears and saliva may improve lubrication and decrease the occurrence of cracking and fissures in mucous membranes. Newer therapies such as cyclosporine ophthalmic emulsion and autologous serum tears have provided relief for chronic ocular GVHD.[162] If nutritional intake is poor, consultation with a clinical nutritionist and use of oral nutritional supplementation may be advisable. Patients should be instructed to apply sunscreens to exposed areas whenever prolonged sun exposure is anticipated. Liver function abnormalities have been improved by up to 30% with the use of ursodiol as bile acid displacement therapy.[118,163,164] Calcium supplements, estrogen

replacement, or other anti-osteoporosis agents should be considered in females or other patients at risk for fracture or bone loss while receiving prolonged regimens with immunosuppressant therapy.[165] Patient education regarding the gradual resolution of symptoms such as skin sclerosis, fatigue and muscle weakness, anticipated duration of therapy, and importance of compliance with oral immunosuppressive therapy is essential.

INFECTIOUS COMPLICATIONS

Opportunistic infections are a major cause of morbidity and mortality after myeloablative and nonmyeloablative HSCT. There are three general periods of infectious risk (Fig. 101-2). During the early period pre-engraftment, particularly for patients undergoing myeloablative HSCT, the primary pathogens are aerobic bacteria, *Candida* spp., and herpes simplex virus (HSV). Chemotherapy-induced mucosal damage creates a portal of entry into the bloodstream for many organisms, such as viridans group *Streptococcus*, *Candida*, and aerobic gram-negative bacteria. Catheter-associated infections have become the leading cause of bacteremia, most notably in the early posttransplant period.[159,161] The routine use of antiviral prophylaxis has decreased the incidence of HSV. Respiratory viruses such as respiratory syncytial virus (RSV), influenza, ad enovirus, and parainfluenza are increasingly recognized as pathogens causing pneumonia, particularly during community outbreaks of infection.[166] To reduce potential exposure of HSCT recipients to these pathogens, visitors and staff members with signs and symptoms of a viral respiratory illness may not be allowed direct contact with patients.

A potential advantage of reduced-intensity or nonmyeloablative preparative regimens is reduced toxicity of the preparative regimen compared to myeloablative HSCT. Reduced-intensity or nonmyeloablative preparative regimens frequently do not result in true neutropenia,[5] and the incidence of mucositis during the early

period is reduced.[167] In a matched controlled study, the incidence of bacteremia during the first 30 days post-HSCT in the nonmyeloablative recipients was significantly reduced compared to myeloablative recipients.[167] Moreover, nonmyeloablative HSCT recipients experienced significantly fewer infections attributable to mucositis during the early period.

The second or middle (see Fig. 101-2) period of infectious risk includes the time from engraftment to posttransplant day +100. Pathogens such as CMV, adenovirus, and *Aspergillus* are common. Adenovirus, CMV, *Aspergillus*, and *P. jirovecii* frequently cause interstitial pneumonitis. Patients undergoing reduced-intensity or nonmyeloablative preparative regimens that experience aGVHD and are treated with corticosteroids have a similar risk of infection during this time period as those undergoing myeloablative HSCT.[169]

During the late period (after day +100), the predominant pathogens are the encapsulated bacteria (eg, *S. pneumoniae*, *H. influenzae*, *Neisseria meningitidis*), fungi/mold, and varicella-zoster virus (VZV). The encapsulated bacteria commonly cause sinopulmonary infections. The risk of infection during this late period is increased in patients with cGVHD as a result of prolonged immunosuppression.

Because of the morbidity associated with opportunistic infection in HSCT recipients, optimal pharmacotherapy for prevention and treatment is critical. In 2009, the U.S. Centers for Disease Control and Prevention (CDC) published guidelines for prevention of opportunistic infection in HSCT recipients.[4,168] These guidelines were constructed from available data by an expert panel from the CDC, the Infectious Disease Society of America, and the American Society for Blood and Marrow Transplantation. The following discussion incorporates recommendations from the CDC guidelines and also provides information on the pharmacotherapy of opportunistic infections in all types of HSCT.

Prevention and Treatment of Bacterial and Fungal Infections

CASE 101-6

QUESTION 1: S.D. is a 26-year-old female with Ph+ acute lymphocytic leukemia in first complete remission who is admitted for allogeneic myeloablative HSCT. The following orders are written: Admit to a room with a positive-pressure high-efficiency particulate absorbing (HEPA) filter. Flush double-lumen Hickman catheter per protocol. Immunosuppressed patient diet as tolerated. Begin fluconazole 400 mg PO every 24 hours and levofloxacin 500 mg PO every 24 hours on admission. Begin ceftazidime 2 g IV every 8 hours with first fever when ANC is <500 cells/μL. Transfuse 2 units of packed RBCs for hematocrit <25% and 1 unit of single-donor platelets for platelet count <20,000/μL.

What is the rationale for these supportive measures?

As a result of disease-related immunosuppression, intensive preparative regimens, and posttransplant immunosuppressive therapy, patients undergoing allogeneic HSCT require careful monitoring for regimen-related toxicities and intensive supportive care directed at maintaining adequate blood counts, preventing or treating infection, and providing optimum nutrition.

Placement of a double-lumen or triple-lumen central venous catheter is mandatory in all patients. The need for administration of chemotherapy, blood products, antibiotics, parenteral nutrition, and adjunctive medications over a prolonged period of time precludes the use of peripheral access sites. The use of a central venous catheter allows delivery of maximum concentrations of all medications into a high-flow blood vessel. Administration time is reduced, and daily fluid infusion is minimized.

After administration of the preparative regimen and before successful engraftment, allogeneic myeloablative HSCT patients undergo a period of pancytopenia lasting from 2 to 6 weeks. During this time, patients may require multiple RBC and platelet transfusions. Packed RBCs and platelets are usually given for a hematocrit <25% and a platelet count <10,000/μL or 20,000/μL. Transfusions with multiple blood products put patients at risk for blood product–derived infection (eg, CMV, hepatitis). In addition, sensitization to foreign leukocyte HLA antigens (alloimmunization) may cause immune-mediated thrombocytopenia. Thus, blood product support in the myeloablative allogeneic HSCT patient must

incorporate strategies that reduce the risk of viral infection and alloimmunization. Effective methods include minimizing the number of pretransplant infusions, using single-donor rather than pooled-donor blood products, irradiating blood products, and filtering blood products with leukocyte reduction filters.

Patients receiving reduced-intensity or nonmyeloablative preparative regimens may or may not experience neutropenia and generally have reduced requirements for blood products. In fact, many centers perform reduced-intensity or nonmyeloablative HSCT in the outpatient setting and admit patients to the hospital only for complications requiring more aggressive management.

Aggressive use of antibacterial, antifungal, and antiviral therapy, both prophylactically and for documented infection, is an important aspect of patient management. Antibiotics with a broad gram-negative spectrum may be instituted prophylactically once the patient becomes neutropenic (ANC >1000 cells/μL), or empirically after the patient is neutropenic and experiences fever (oral temperature >100.40 °F [>38 °C]). Some transplant centers administer a prophylactic fluoroquinolone such as levofloxacin on admission especially if the neutropenic period is expected to extend beyond 7 days.[169-173]

Fluoroquinolone prophylaxis during periods of neutropenia significantly reduces the incidence of gram-negative bacteremia but generally does not affect mortality.[4] Concerns regarding prophylactic fluoroquinolone use include the emergence of resistant organisms and an increased risk of streptococcal infection.[4,174] In fact, the incidence of *Viridians* group of streptococci has been increasing.[4,175] Prophylactic antibiotics (eg, penicillin, vancomycin) are not recommended because of their lack of proven efficacy in preventing streptococcal infections and the concern about antibiotic-resistant bacteria.[4] Regardless of prophylactic strategies, patients who become febrile during neutropenia should immediately receive broad-spectrum IV antibiotic(s) (eg, ceftazidime, cefepime, imipenem, or meropenem) and prophylaxis should be discontinued.[4,176]

Antifungal prophylactic agents are commonly used in HSCT recipients. S.D. is prescribed fluconazole 400 mg/day on admission because prophylactic use until day +75 posttransplant decreases the incidence of systemic fungal infection and fungal death in patients undergoing HSCT.[177,178] The use of prophylactic fluconazole has been linked to reports of breakthrough infections with resistant fungi such as *C. glabrata* and *Aspergillus*.[179,180]

When broader yeast and mold prophylaxis is required, either posaconazole or voriconazole may be used. If S.D. were to require mold prophylaxis, voriconazole 200 mg twice daily would be a reasonable choice. Voriconazole 200 mg twice daily was compared to fluconazole 400 mg once daily in a randomized double-blind trial for the prevention of invasive fungal infections in standard risk HSCT. No significant differences were seen in fungus-free survival, relapse-free status, and overall survival at 6 months. Toxicities were similar, and there was a trend toward reduced *Aspergillus* infections and less empiric antifungal therapy in the voriconazole arm.[181] Posaconazole has also been used for mold prophylaxis in HSCT based on its efficacy as prophylaxis in neutropenic patients.[182] Both azoles affect the CYP3A4 isoenzyme, and their use with calcineurin inhibitors requires judicious monitoring. The use of broader spectrum azoles has also resulted in the development of breakthrough zygomycosis infections, particularly with the use of voriconazole.[183]

The echinocandins have also been used for broader yeast and mold prophylaxis in HSCT. Micafungin (50 mg IV every 24 hours) and fluconazole (400 mg IV every 24 hours) were compared in a randomized, double-blind study of patients undergoing HSCT. Overall success was defined as the absence of suspected, proven, or probable systemic fungal infection through the end of therapy and as the absence of proven or probable systemic fungal infection through the end of the 4-week posttreatment period. The overall efficacy was greater in the patients who received micafungin (80.0% vs 73.5% P = .03). Fewer episodes of aspergillosis occurred in patients treated with micafungin.[184]

Prevention of Herpes Simplex Virus and Varicella-Zoster Virus

Case 101-6, Question 2: On routine screening before transplantation, S.D. is found to be HSV-seropositive (≥1.11 index value) and VZV-seropositive (≥1 index value). How will this affect her management?

Up to 70% of HSV-seropositive patients undergoing myeloablative allogeneic HSCT will experience reactivation of HSV.[185] Prophylactic acyclovir is commonly used in HSV-seropositive patients undergoing allogeneic or autologous HSCT to prevent viral reactivation.[4,186] Dosing regimens for prophylactic acyclovir vary widely; the dose of IV acyclovir is typically 250 mg/m^2 IV every 8 hours, whereas oral doses of acyclovir range from 600 to 1600 mg/day.[4] The recommended duration of acyclovir prophylaxis for HSV varies from day +30 to day +365 posttransplant or longer, depending on the specific type of HSCT and other risk factors. Valacyclovir, a prodrug of acyclovir with improved bioavailability, provides sufficient blood concentrations to prevent HSV in patients with mucositis or GI aGVHD.[187] Prophylactic valacyclovir is commonly used at a dose of 500 mg PO every 12 hours.[188,189]

Patients who are VZV-seropositive are at risk for developing herpes zoster, particularly after day +100 posttransplant.[190] Prophylactic acyclovir reduces the risk of VZV reactivation.[191] As with prophylaxis for HSV reactivation, the optimum duration of VZV prophylaxis is controversial, often extending to day +365 posttransplant or longer.

Patients who are HSV-seronegative or VZV-seronegative rarely exhibit primary HSV or VZV infection and are therefore not administered prophylactic acyclovir. If HSV does occur, lesions usually appear on the oral mucosa, nasolabial mucous membranes, or genital mucocutaneous area and can be managed with acyclovir at standard treatment doses.

Because S.D. is HSV- and VZV-seropositive, she is at risk for viral reactivation and should receive prophylactic acyclovir 400 mg PO

twice daily, beginning 4 days prior to transplant and continuing until her ANC is >2500 cells/μL for at least 2 days.

Prevention of Cytomegalovirus Disease

Case 101-6, Question 3: S.D. is also CMV-seropositive. What is the significance of this finding and what measures can be taken to prevent reactivation of CMV?

Cytomegalovirus has the ability to establish lifelong latent infection after primary exposure. In patients who are immunocompromised, the virus may reactivate, resulting in asymptomatic shedding or the development of CMV disease. The incidence of CMV infection (defined as isolation of the virus or detection of viral proteins or nucleic acid in any body fluid without clinical symptoms) and CMV disease (signs and symptoms consistent with CMV invasion into a tissue) in HSCT recipients is 15% to 60% and 20% to 35%, respectively. The most common manifestations of CMV disease after allogeneic HSCT are pneumonitis, fever, and GI infection.[192]

In the CMV-seronegative HSCT recipient, primary CMV infection or disease can be prevented by selecting a CMV-seronegative donor and using only blood products from CMV-seronegative donors. No anti-CMV prophylaxis is required in these recipients. In patients who are CMV-seropositive or who have received a CMV-seropositive graft, antiviral drugs are essential to minimize morbidity associated with CMV reactivation or secondary infection. Two general strategies are possible. One strategy involves preemptive therapy or risk-adjusted therapy.[187,193,194] Using this strategy, patients begin therapy only if they have early reactivation of CMV detected through the assay of blood for CMV antigens (eg, pp65) or viral nucleic acid using polymerase chain reaction (PCR) testing. Using preemptive therapy selectively administers ganciclovir to only those HSCT patients at greatest risk for development of CMV disease.[195–197] Antigenemia-based preemptive therapy is as effective as universal ganciclovir prophylaxis for the prevention of CMV disease and is

associated with reduced CMV mortality.[198,199–202] The induction dose of ganciclovir is typically 5 mg/kg IV every 12 hours for 7 to 14 days, followed by a maintenance dose of 5 mg/kg IV daily until 2 to 3 weeks after the last occurrence of antigenemia or until day +100 posttransplantation.[4] Preemptive therapy limits patient exposure to the potential toxicity of ganciclovir and thus reduces overall cost.[190] Oral valganciclovir is a safe and effective alternative to IV ganciclovir for preemptive therapy.[203,204] The other strategy that can be employed is the use of the antiviral letermovir. A phase-3, double-blind trial showed that letermovir is effective as prophylaxis in patients who are CMV-seropositive. Its use resulted in a clinically significant decrease in the development of CMV infection in patients undergoing HSCT.[205]

Foscarnet may also be administered, but its use is complicated by nephrotoxicity and electrolyte wasting.[202,206] Monitoring and correction of electrolyte and fluid imbalances are essential when foscarnet is initiated.

Cidofovir is used to treat CMV in patients undergoing HSCT but is reserved for use when other agents have failed.[207] Dose-related renal dysfunction, which can be seen after even one or two doses, limits the number of patients able to receive cidofovir.[207] An advantage of cidofovir is its infrequent dosing, making it conducive to clinic administration. Monitoring renal function, electrolytes, WBC, and intraocular pressure are essential monitoring parameters.

Autologous HSCT recipients who are CMV-seropositive pretransplant should receive antiviral treatment preemptively as described.[4,208] Nonmyeloablative or reduced-intensity HSCT recipients should also receive preemptive antiviral treatment. Because host T cells may persist in the peripheral blood for up to 6 months after reduced-intensity or nonmyeloablative preparative regimens, their presence may provide some protection against early CMV disease. A matched controlled study comparing the incidence and outcome of CMV infection in myeloablative and nonmyeloablative HSCT demonstrated that although the time to onset of CMV antigenemia was similar in the two groups, fewer nonmyeloablative HSCT recipients experienced CMV disease in the

early period.[209] The overall 1-year incidence of CMV disease was also similar, suggesting that nonmyeloablative HSCT recipients are at increased risk for exhibiting late CMV disease (>100 days after transplantation) compared to their myeloablative counterparts.[209] It is therefore recommended that nonmyeloablative HSCT patients receive preemptive antiviral therapy and be monitored for development of CMV antigenemia for 1 year after HSCT.[209,210]

S.D.'s ANC recovers to >1000 cells/μL on day +20, and on day +32, her weekly surveillance blood sample is positive for CMV by PCR. Preemptive ganciclovir induction is initiated at 5 mg/kg IV every 12 hours for 2 weeks followed by maintenance dosing of 5 mg/kg daily. After 3 weeks of therapy, S.D.'s surveillance samples are negative and ganciclovir is discontinued. Weekly surveillance sampling continues until day +100. If surveillance samples again become positive for CMV, ganciclovir therapy should be reinstituted.

Diagnosis and Treatment of Aspergillus Infection

RISK FACTORS

CASE 101-7

Question 1: A.W., a 132.27 pounds (60 kg), 64.96 inches (165 cm), 15-year-old boy, is day +79 after a matched, unrelated, nonmyeloablative PBPC transplant for acute lymphocytic leukemia in third complete remission. He presents to the clinic for evaluation of a temperature of 102.30 °F (39.05 °C) and a 3-day history of nonproductive cough. Significant medical history includes skin and GI GVHD (stable on his current regimen of cyclosporine, mycophenolate mofetil, and prednisone) and congestive heart failure believed to be secondary to anthracycline exposure. A.W. has chronic low-grade nausea and hypomagnesemia necessitating daily IV hydration with magnesium supplementation. Relevant laboratory values are as follows:

Na, 138 mEq/L
K, 4.2 mEq/L
Cl, 100 mEq/L
CO_2, 23 mEq/L
Blood urea nitrogen, 18 mg/dL
SCr, 0.8 mg/dL

Total bilirubin, 0.6 mg/dL
Mg, 1.5 mg/dL
WBC count, 3500 cells/μL
Platelets, 78,000/μL
ANC, 1810 cells/μL
Hemoglobin, 10.8 g/dL

He was CMV-seropositive and HSV-seropositive before HSCT. Oral medications include cyclosporine 275 mg every 12 hours, mycophenolate mofetil 900 mg every 12 hours, prednisone 60 mg every morning and 12.5 mg every evening (tapering), trimethoprim–sulfamethoxazole (TMP/SMX) 160 mg/800 mg twice daily on Monday and Tuesday, posaconazole 300 mg every morning, valacyclovir 500 mg bid, digoxin 0.125 mg every 12 hours, enalapril 10 mg every 12 hours, and a multivitamin every morning.

On physical examination, A.W. is a chronically ill-appearing child with “moon” face, dry skin with thickened areas, a pleural friction rub, and thinning hair. Blood cultures, urinalysis, and chest x-ray are obtained. Chest x-ray reveals several small cavitary lesions worrisome for fungal disease. A.W. is admitted for further workup and management of presumed *Aspergillus* infection.

What risk factors does A.W. have for developing an infection with *Aspergillus?*

Invasive molds (most commonly *Aspergillus* spp., but also *Fusarium* spp., *Scedosporium*, and *Zygomycetes*) are an increasing cause of morbidity and mortality after allogeneic and autologous HSCT. A major factor contributing to this trend includes more effective prevention of bacterial and viral infection that promotes mold overgrowth, as described.[177–179,211,212] *Aspergillus* infection is reported in up to 26% of HSCT recipients, and the mortality rate of invasive aspergillosis (IA) is 74% to 92%.[184]

Several risk factors for the development of invasive fungal infection have been identified.[211,212] Given that neutrophils are critical for host defense, prolonged neutropenia is considered the single most important predictor of infection at any point after HSCT.[180,211] GVHD (acute and chronic) and treatment with corticosteroids are also important risk factors, particularly for aspergillosis, presumably as a result of neutrophil dysfunction.[184,211–213] In addition, the widespread use of fluconazole prophylaxis (400 mg/day) for the prevention of invasive candidiasis in patients undergoing transplant since the early 1990s has led to a substantial increase in the

incidence of IA and also fluconazole-resistant *Candida* species such as *Candida krusei* and *Candida glabrata*.[211,213,214]

A.W. is receiving corticosteroid treatment for GVHD and posaconazole prophylaxis. These therapies increase his risk for exhibiting IA.

TREATMENT

Case 101-7, Question 2: A.W. undergoes bronchoalveolar lavage to identify the organism responsible for his pulmonary infection. Pathologic examination of the fluid obtained reveals septate and branching hyphae, and culture results confirm the diagnosis of *Aspergillus fumigatus* infection. Imaging scans are negative for extrapulmonary involvement. How is aspergillosis usually diagnosed, and what are the acceptable alternatives for treating this infection?

Early diagnosis and treatment of IA, which rely on tissue or fluid obtained from the infected site followed by aggressive antifungal therapy, may improve patient survival.[215] Although the lower respiratory tract is frequently the primary focus of infection, *Aspergillus* may invade blood vessels and spread hematogenously to other organs, including the brain, liver, kidneys, spleen, and skin.[190] Head, chest, abdomen, and pelvic computed tomography scans assist in assessing the extent of disease, treatment options, and overall prognosis. Cultures of respiratory tract secretions lack sensitivity for detecting *Aspergillus*, and the medical condition of the patient may preclude invasive diagnostic procedures altogether. Many clinicians have adopted the European Organization for Research and Treatment of Cancer criteria for diagnosis of proven, probable, and possible IA.[216]

Newer diagnostic tests based on the detection of fungal antigens or metabolites, such as galactomannan, 1,3-β-D-glucan, and fungal DNA detection by PCR, are now being used. Galactomannan is a polysaccharide component of the *Aspergillus* cell wall that is released during fungal cell growth. Galactomannan detection by enzyme-linked immunoassay (GM-EIA) has proved to be a sensitive and specific tool for the early detection of *Aspergillus* infection. The

test is useful not only for serum samples but also for bronchoalveolar lavage and cerebrospinal fluid. Concomitant antifungal therapy may cause false-negative results, whereas antibiotics of fungal origin (eg, piperacillin/tazobactam) have been associated with false positives.[184,217]

ANTIFUNGALS

Outcomes for patients with IA after HSCT are often poor, with ~20% of patients alive after 1 year.[211] Treatment success depends not only on the use of intensive antifungal agents but also on recovery of the host immune system and/or reduction of immunosuppression.[215,218] Conventional amphotericin B had traditionally been the gold standard antifungal therapy for IA with response rates in the range of 28% to 51%, depending on the severity of the underlying immunosuppression; however, 65% of responders eventually died of their infection.[215] Fortunately, broad-spectrum triazoles and echinocandins are available as alternatives. The treatment of IA has moved away from the use of amphotericin to the use of broad-spectrum azoles for its treatment.

Three broad-spectrum triazole agents (voriconazole, posaconazole) are available for patients. Voriconazole is one of the newer broad-spectrum azoles whose advantage is its excellent (96%) oral bioavailability. Voriconazole has been compared to conventional amphotericin B in a randomized, unblinded trial as primary therapy for established IA in an immunocompromised host.[219] The primary objective was to demonstrate the noninferiority of voriconazole compared with conventional amphotericin B after 12 weeks of therapy in patients with definite or probable IA. Patients received voriconazole 6 mg/kg IV every 12 hours for two doses followed by 4 mg/kg IV every 12 hours for at least 7 days, followed by oral voriconazole 200 mg every 12 hours or amphotericin B at a dose of 1 to 1.5 mg/kg/day. Patients refractory to or intolerant of initial therapy could receive other antifungal drugs. Of 144 evaluable patients who received voriconazole, 76 (52.8%) had a partial or complete response compared to 42 of 133 (31.6%) patients treated

with amphotericin B. The median duration of therapy for patients treated with voriconazole was 77 days, and 52 of 144 patients switched to an alternative agent. In contrast, the median duration of therapy for patients receiving amphotericin B was 10 days, and 107 of 133 patients switched to another agent (most commonly, a lipid formulation of amphotericin B). The survival rate at 12 weeks in the voriconazole group was 70.8% compared to 57.9% (P = .02). These results of initial therapy with voriconazole indicate superior response and improved survival in patients who are immunocompromised, such as allogeneic HSCT recipients, with IA. Patients treated with voriconazole also experienced fewer drug-related adverse effects; however, drug interactions because of P450 3A4 inhibition should be closely monitored.

Posaconazole, the newest broad-spectrum triazole, is available as an oral suspension, oral tablets, and an intravenous formulation. The oral suspension has a more variable absorption as compared to the tablet formulation. In general, posaconazole has the lowest minimum inhibitory concentration of any available triazole against *Aspergillus* spp., including *Aspergillus terreus*. It is the only triazole with activity against the *Zygomycetes*. In an open-label externally controlled trial in patients with IA refractory to or intolerant of other therapies, the overall success rate was 42% in patients treated with posaconazole compared to 26% for controls (P = .006).[220]

Echinocandin antifungal agents (caspofungin, micafungin) inhibit the synthesis of β-(1,3)-glucan, an important component of the fungal cell wall. No prospective randomized trials have documented the efficacy of any echinocandin for primary therapy of IA, and only caspofungin is approved for salvage therapy. An open-label, noncomparative trial evaluated the efficacy of caspofungin in 69 patients who had failed or were intolerant of at least 7 days of standard antifungal therapy.[221] Patients received 70 mg IV of caspofungin on day 1 followed by 50 mg IV daily. Of the 63 evaluable patients, 26 (43%) responded favorably to treatment. Twenty-six of 52 patients (50%) who had received at least 7 days of therapy had a favorable response. In another open-label, noncomparative trial, Denning et al evaluated the safety and efficacy

of micafungin (alone or in combination) in patients with proven or probable aspergillosis. Eighty of 225 patients (35.6%) had a favorable response. Most patients received combination therapy; the 34 patients treated with monotherapy had a similar response rate.[222] Amphotericin B is no longer first-line therapy for the treatment of IA. It is typically reserved for patients who develop mold infections, such as cryptococcus, that are resistant to the azoles.

The most common toxicities associated with azole treatment include elevations in hepatic transaminase enzymes and alkaline phosphatase. The azoles are also known inhibitors of the CYP3A4 isoenzyme; therefore, drug interaction monitoring is imperative. The major interaction seen in patients undergoing allogeneic HSCT is an increase in calcineurin inhibitor levels. Careful monitoring is warranted. Voriconazole has been associated with visual disturbances (blurred vision, altered color perception, photophobia, visual hallucinations).[223]

In summary, the number of agents available to manage IA has expanded greatly in the past decade. Therapy should be tailored to the individual patient based on response, tolerability, and cost.

Prevention of *Pneumocystis jirovecii* Pneumonia

Case 101-7, Question 3: A.W. is receiving TMP/SMX, one double-strength tablet PO bid on Monday and Thursday. What is the rationale for its use?

Pneumocystis jirovecii is a common pathogen that causes *Pneumocystis* pneumonia (PCP) in patients who have undergone allogeneic HSCT. PCP is a potentially lethal infection, and prophylaxis is routinely administered. The optimum prophylactic regimen has not been established, but most centers administer TMP/SMX for PCP prophylaxis.[4] Dapsone, atovaquone, and aerosolized pentamidine are alternatives for patients who are allergic to sulfonamides or do not tolerate TMP/SMX for other reasons such as hematologic toxicities. PCP prophylaxis is usually begun after neutrophil recovery because (a) PCP most commonly occurs after

engraftment and (b) TMP/SMX is potentially myelosuppressive. Patients should be closely monitored for unexplained neutropenia or thrombocytopenia.

Issues of Survivorship after Hematopoietic STEM Cell Transplantation

CASE 101-8

QUESTION 1: H.O. is a 32-year-old female who received a BU/CY preparative regimen and an HLA-matched sibling HSCT for the treatment of chronic phase CML at age 21 years. H.O. received her HSCT more than 10 years ago, is disease-free, and has not had cGVHD for 9 years. Her only medication is one multivitamin tablet daily.

What issues of cancer survivorship are of concern to H.O.?

A greater proportion of HSCT recipients are surviving their cancer diagnosis without evidence of their primary malignancy, but they are at risk for long-term physical and emotional sequelae of their cancer treatments.[2] Many long-term HSCT survivors are no longer under the care of an HSCT center, and their health care providers may be unfamiliar with the complications of HSCT. To facilitate the clinical care of long-term HSCT recipients, recommendations for screening and preventive practices have been created for adult and pediatric HSCT survivors.[224,225] These guidelines should facilitate the provision of health care to HSCT recipients. The following paragraphs describe various concerns associated with the morbidity of long-term HSCT survivors.[224–226] Long-term HSCT survivors should be regularly screened for the development of secondary malignancies and complications of GVHD that affect the oral mucosa, liver, respiratory, endocrine, ocular, skeletal, nervous system, kidney, and vascular systems. The psychosocial health of HSCT survivors should also be evaluated.

Immune function can take >2 years to recover, even after discontinuation of immunosuppressants.[227] Treatment of GVHD exacerbates immune system defects, necessitating prophylaxis and vigilant monitoring for infectious complications. Fevers should be rapidly assessed and treated to prevent fatal infections. Recipients of HSCT also lose protective antibodies to vaccine-preventable diseases; therefore, HSCT survivors need to be revaccinated for selected infectious diseases with due consideration for the risk of vaccination.

Hematopoietic cell transplant survivors have a greater risk of secondary malignant neoplasms.[2] An increased incidence of cancer of the skin, oral mucosa, brain, thyroid, and bone is observed after allogeneic HSCT, and an increased incidence of myelodysplasia and acute leukemia can occur after autologous HSCT for NHL.[2] Survivors should avoid carcinogens (eg, tobacco) and be screened for secondary malignant neoplasms indefinitely.[2] Long-term impairment of end-organ function may be because of the preparative regimen, infectious complications (either autologous or allogeneic grafts), and posttransplant immunosuppression (allogeneic grafts only).[224,226] Endocrine dysfunction, specifically of the thyroid, gonads, and growth velocity, is common.[224,225] Adrenal insufficiency can result from long-term corticosteroid therapy used to treat GVHD. Infertility is commonly observed after myeloablative HSCT secondary to the high doses of alkylating agents and radiation administered. Frequently, males become azoospermic, and chemically induced menopause develops in females.[2] However, pregnancies have occurred after HSCT.[2] Up to 60% of HSCT recipients have osteopenia, most likely resulting from gonadal dysfunction and corticosteroid administration; avascular necrosis because of corticosteroids can also occur.[227] A significant portion (15%–40%) of HSCT survivors exhibit pulmonary dysfunction with variable symptoms (eg, restrictive, chronic obstructive lung disease) from multiple causes.[228] Hepatic infections can occur in HSCT recipients through blood transfusions or, more commonly, because recipients or donors have a latent hepatitis viral infection. The prevalence of chronic hepatitis C ranges from 5% to 70% in long-term HSCT

survivors.[229] Because of this, cirrhosis and its complications may become an important late complication of HSCT.[229] Hepatic dysfunction can also result from iron overload, which may occur secondary to multiple RBC transfusions administered during aplasia after myeloablative preparative regimens and before HSCT. Alopecia is a common late effect with BU/CY, as are cataracts with CY/TBI.[77]

H.O. should be routinely monitored for signs of relapse and cGVHD. To lower the risk of infectious complications, she should be counseled to obtain prompt medical care for fevers or signs of an infection, and she should be revaccinated if she has not done so since receiving her myeloablative HSCT. Thorough evaluation of end-organ function, including renal, hepatic, thyroid, and ovarian function, should be assessed at regular intervals. In addition, her bone mineral density should be determined, and H.O. should be counseled on preventive measures for osteopenia (eg, calcium supplementation). In addition to standard cancer screening tests, H.O. should be closely monitored for secondary malignant neoplasms.[2]

Pediatric Pharmacotherapy

Elizabeth Anne Farrington

CORE PRINCIPLES		CHAPTER CASES
GROWTH AND DEVELOPMENT		
1	Children undergo considerable physiologic changes between birth and adulthood. Although most follow the same general pattern of growth, the timing of maturation varies from child to child.	**Case 102-1 (Question 1), Table 102-1**
PHARMACOKINETIC DIFFERENCES		
1	All aspects of pharmacokinetics are affected by growth and development. Drug absorption is altered by a variety of mechanisms, with the most significant differences noted during the first months of life.	**Case 102-2 (Question 1) Case 102-3 (Question 1–4)**
2	Drug distribution is affected by changes	**Case 102-3 (Question 5, 6),**

	in relative organ size, body water content, fat stores, plasma protein concentrations, acid–base balance, cardiac output, and tissue perfusion. The greatest degree of change occurs during the first year of life.	**Table 102-2**
3	Metabolic function is highly dependent on patient age. This has been demonstrated in a number of recent studies, which have identified significant differences in half-life during infancy, childhood, and adolescence.	**Case 102-4 (Question 1–4)**
4	Elimination is reduced during infancy, resulting in slower rates of clearance for many commonly used drugs. Glomerular filtration rate increases throughout childhood. Use of creatinine clearance as an estimate of glomerular filtration rate requires different equations than those used in adults.	**Case 102-5 (Question 1, 2)** **Case 102-6 (Question 1)**
5	Adolescence is not simply a link between childhood and adulthood; it is a distinct period of significant physiologic change. The effects of puberty can alter the efficacy or toxicity of many drugs administered during this period.	**Case 102-7 (Question 1)**
PHARMACODYNAMIC DIFFERENCES		
1	Although less well understood than pharmacokinetic differences between children and adults, there are significant age-related effects on pharmacodynamics as well. Children	**Case 102-8 (Question 1)** **Case 102-9 (Question 1, 2)**

	may exhibit differences in both therapeutic response and adverse effect profiles.	
MEDICATION DOSING IN CHILDREN		
1	The differences in pharmacokinetics and pharmacodynamics observed in children influence the choice of drug dose and dosing interval. For most dose calculations, weight is used to account for growth and development.	**Case 102-10 (Question 1)**
2	All pediatric prescriptions and medication orders must be checked for the appropriateness of the dose, route, and frequency with a pediatric dosing reference.	**Case 102-10 (Question 1)**
PREVENTING MEDICATION ERRORS IN CHILDREN		
1	Children are at a greater risk for medication errors than adults, as a result of the need to calculate drug doses and alter dosage formulations.	**Case 102-10 (Question 2)**
2	Electronic prescribing, standardization of drug doses and concentrations, and the introduction of smart-pump technology have been shown to reduce errors in many children's hospitals. One of the most effective methods to avoid errors is the inclusion of pediatric pharmacists in the medication ordering and review process.	**Case 102-10 (Question 3), Table 102-3**
INCREASING PEDIATRIC MEDICATION INFORMATION		

1	A number of governmental programs are increasing the availability of pediatric medication information and improving the ability of pediatric health care professionals to provide safe and effective drug therapy for children.	**Case 102-10 (Question 4)**

INTRODUCTION

Providing care for children can be one of the most challenging, but rewarding, aspects of pharmacy practice. Although a relatively small number of health care providers pursue specialty training in pediatrics and work exclusively with children, most clinicians will provide care for children every day in the community or hospital setting. According to recent population estimates, ~22.3% of the U.S. population is younger than age 18 years, with 6% younger than age 5 years.[1] Although most children are healthy, this segment of the population still uses a significant amount of health care resources. In a recent telephone survey, one in five parents reported giving their child one or more prescription medications within the previous week.[2] A survey conducted in pediatricians' offices found that 53% of children left their visit with a prescription.[3]

Pediatrics, as a specialty, encompasses a very diverse patient population. Patients range in age from premature neonates to adolescents and can vary in weight by 300-fold, from a 1.10-pound (0.5-kg) premature neonate to a 330.69-pound (150-kg) 16-year-old. Further complicating the care of children is the relative lack of information on drug dosing and monitoring. Because of the small numbers of children requiring medical treatment and the difficulty in conducting research in these patients, fewer than half of the drugs currently available in the United States are approved by the U.S. Food and Drug Administration (FDA) for pediatric use.[4,5] As a result, as many as 60% of all prescriptions written by pediatricians are for

"off-label" uses.[6] Dosing and monitoring information for off-label uses is often based on case series and clinical trials published in the medical literature and may not be readily available in general drug references.

Health care providers caring for children must be capable of assessing the appropriateness of drug doses for this diverse population and providing recommendations for dosage adjustments and patient monitoring with limited resources. This requires knowledge of the pharmacokinetic and pharmacodynamic differences between children and adults and how these differences impact both therapeutic and adverse drug effects.

GROWTH AND DEVELOPMENT DURING CHILDHOOD

CASE 102-1

QUESTION 1: C.J. is a 4-month-old, 14.33-pound (6.5-kg) male who has recently started teething. His parents ask for advice on a medication to alleviate C.J.'s pain.

What factors will influence your decision about the choice of medication and dosing regimen for C.J.? What medication and dose will you recommend to his parents?

Children undergo considerable physiologic changes between birth and adulthood. Although many changes are easily observed, such as the ability to walk or the development of language, others are less evident. C.J.'s analgesic dose will be based on his age and weight, as estimates of the numerous pharmacokinetic and pharmacodynamic differences between children and adults. To discuss the changes that occur with growth and development, pediatric patients are typically grouped by age (**Table 102-1**). These definitions are helpful to provide a consistent framework for dosing recommendations, but it should be kept in mind that they are

arbitrary and can oversimplify the differences among individual patients. Although children tend to grow and develop in a relatively similar manner, the timing of maturation varies from child to child. Children do not grow in a predictable, linear fashion, but rather in periodic bursts, with additional variation caused by differences in genetic predisposition, nutritional intake, and environment.[7,8] Research on the impact of growth and development on pharmacokinetics and pharmacodynamics, often referred to as developmental pharmacology, has grown considerably during the past several decades, improving our ability to optimize the efficacy of drug therapy in children while minimizing adverse effects.

Table 102-1
Commonly Used Age Definitions

Premature Neonate	Born at >36 Weeks' Gestational Age
Term neonate	Born at ≥36 weeks' gestational age
Neonate	Birth–1 month of age
Infant	>1 month–1 year of age
Child	>1–11 years of age
Adolescent	12–16 years of age

The most appropriate analgesic for C.J. would be acetaminophen. Aspirin is no longer used as an analgesic in children because of its association with Reye syndrome, a rare condition causing mitochondrial damage and resulting in hepatic failure. Nonsteroidal anti-inflammatory drugs, such as ibuprofen, are not recommended for use in infants younger than age 6 months because of unknown effects on the developing kidney.[9] C.J. should receive an acetaminophen dose of 10 to 15 mg/kg given every 4 to 6 hours as needed, with no more than five doses or 75 mg/kg given in a 24-hour period. Based on his age and weight, an appropriate recommendation for C.J. would be to give 65 mg (2 mL) of the acetaminophen 160 mg/5 mL oral suspension by mouth every 6

hours as needed. If C.J. continues to need medication for >24 hours, his parents should contact C.J.'s primary health care provider.

PEDIATRIC PHARMACOKINETIC DIFFERENCES

All aspects of pharmacokinetics are affected by growth and physical maturation, beginning during gestation (pregnancy) and ending in adulthood. These changes are complex, and their timing can vary widely from patient to patient.

Drug Absorption

ORAL DRUG ABSORPTION

CASE 102-2

QUESTION 1: A.H., a 3.30-pound (1.5-kg), 4-week-old female born at 29 weeks' gestational age, is being treated with phenobarbital for seizures associated with a period of asphyxia at birth. She is currently receiving a maintenance dose of 7.5 mg (5 mg/kg) given intravenously (IV) once daily. The team wishes to transition her to oral therapy now that she is receiving full enteral feeds. A trough serum phenobarbital concentration obtained during IV therapy was 17.5 µg/mL, within the desired range of 15 to 40 µg/mL. Switching the patient to phenobarbital elixir 7.5 mg given orally once daily results in a serum concentration of only 8.9 µg/mL after 1 week of therapy.

What factors might explain the lower concentration, and how should A.H. be managed?

Enteral absorption of drugs is altered at birth and does not approximate adult patterns for several months.[7,8] Gastric fluid volume is greatly reduced at birth. Gastric acid production is decreased, giving the neonate a higher, nearly neutral pH in the stomach. This results in a greater absorption of acid-labile drugs such as penicillin G and erythromycin, but reduced absorption of

weakly acidic drugs such as phenobarbital and phenytoin. Gastric acid output increases during the first 1 to 2 weeks of life but only reaches adult values at age 2 to 3 years. Transport of bile acids into the gastrointestinal lumen and pancreatic enzyme production are also reduced, further altering the absorption of pH-sensitive drugs and reducing enterohepatic recirculation. Amylase activity is minimal at birth and remains low until the third month of life.[10] Pancreatic lipase activity is detectable by 32 weeks' gestational age, but remains low at birth and throughout the next 2 to 3 months. In contrast, gastric lipase is present at birth and accounts for a greater percentage of fat absorption during early life. In addition to these differences, neonates are also born with relatively sterile gastrointestinal tracts. Normal bacterial colonization typically occurs within days for term infants but may be delayed in premature infants who reside in the more sterile environment of an intensive care unit. The effectiveness of drugs that rely on gastrointestinal flora for activation or degradation may be significantly altered during this period.

Gastric emptying time is delayed, and intestinal transit time is prolonged at birth, but both quickly increase within the first few days of life because contractions in the stomach become more coordinated and intestinal contractions become more frequent, stronger, and sustained. Premature infants have delayed development of normal gastric emptying and intestinal transit, as shown in a study of acetaminophen dosing in which premature infants at 28 weeks' gestational age had a 2-hour delay in absorption compared with older infants.[11] Adult values for gastric emptying and intestinal transit time are generally reached by age 4 to 8 months.

For drugs absorbed through passive diffusion, reduced splanchnic blood flow during the first weeks of life can reduce the rate and extent of absorption by altering concentration gradients across the intestinal villi.[7] Reduction in blood flow may also place neonates at risk for damage to the gut lining from hyperosmolar drug formulations. As a result, many institutions delay use of the enteral route in premature neonates for drug administration until the patient is receiving at least one-quarter to half of their nutritional needs

through enteral feedings. This allows dilution of drug doses and may reduce the risk for mucosal damage. Lower levels of metabolic enzyme activity in the intestine may reduce first-pass metabolism of drugs given enterally.[12,13] Boucher et al[13] found that the bioavailability of zidovudine decreased from 89% in neonates during the first 2 weeks of life to 61% in older infants, reflecting increased first-pass metabolism in the older patients. Intestinal enzymatic activity does not approach adult values until age 2 to 3 years.

The lower phenobarbital serum concentration after A.H. was placed on enteral therapy is most likely the result of reduced drug absorption in the gastrointestinal tract, resulting from the higher gastric pH and reduced splanchnic blood flow. The maintenance phenobarbital dose for A.H. should be increased to achieve a trough serum concentration within the desired range. An increase of the oral dose to 10 mg would be appropriate, with a plan to obtain a trough concentration within 3 to 5 days. Although this value will not yet reflect the steady-state concentration, because of the long half-life of the drug, it will be useful to guide additional dosing changes.

INTRAMUSCULAR DRUG ABSORPTION

CASE 102-3

QUESTION 1: C.B. is a 7.94-pound (3.6-kg) newborn male, born at 39 weeks' gestational age, who was transferred to the newborn nursery after delivery. Routine care for neonates during the first hours of life generally includes administration of erythromycin eye ointment for prevention of neonatal ophthalmia and 1 mg of phytonadione (vitamin K_1) given intramuscularly (IM) to prevent vitamin K–deficiency bleeding of the newborn. C.B.'s parents question the need to give their baby a shot so soon after birth.

How would you explain the rationale for giving phytonadione IM rather than orally?

In the United States, phytonadione is typically given by IM injection after birth. Drug administration by IM injection typically results in a delay in time to reach peak serum concentrations in neonates. This delay is related to reduced muscle size, weaker muscle contractions,

and an immature vasculature resulting in more erratic blood flow to and from the muscle.[7,8] Although considered a disadvantage when rapid absorption is needed, such as with antibiotic administration, the delay in systemic absorption after IM injection is used as an advantage for the administration of phytonadione after birth. The delayed absorption from muscle results in a depot-like effect, providing a slow release of the drug into the systemic circulation until the infant's dietary intake is adequate to maintain necessary vitamin K serum concentrations.[14] A similar delay in drug absorption may occur with subcutaneous injection because of the lower percentage of body fat in neonates. The delay in absorption seen with IM and subcutaneous administration becomes negligible after the first months of life. When counseling C.B.'s parents, it will be important to stress the benefit of the slower absorption of vitamin K with IM administration compared with the rapid absorption and clearance of a single oral dose. A single IM injection of vitamin K will protect their son from bleeding until he is approximately a month old, when he should be taking in enough breast milk or infant formula to maintain adequate vitamin K concentrations.

TRANSDERMAL DRUG ABSORPTION

Case 102-3, Question 2: C.B. is scheduled for a circumcision before discharge. The surgical site will be prepped with a 10% povidone–iodine solution. What factors influence the absorption of medications via this route in the neonatal patient? Based on these factors, how should the povidone–iodine be applied to minimize toxicity?

In contrast to enteral, IM, and subcutaneous administration, transdermal or percutaneous administration results in greater drug absorption in neonates than it does in older children and adults. Enhanced absorption results from a greater skin to body surface area ratio, approximately three times that of adults, as well as a thinner stratum corneum, better epidermis hydration, and greater perfusion.[7,8] The greater degree of percutaneous absorption in infants has resulted in significant toxicity. Hexachlorophene, when

used routinely to bathe infants, has resulted in seizures and is now considered contraindicated in this age range. Application of povidone–iodine as a topical disinfectant before surgery has been linked to neonatal thyroid dysfunction and, as a result, is now used only in limited quantities for brief periods to limit percutaneous iodine absorption. In spite of the knowledge of this adverse effect, cases continue to be reported in the medical literature.[15] Even relatively common topical products can produce systemic toxicity. Frequent use of diaper rash products containing hydrocortisone can produce suppression of the hypothalamus–pituitary–adrenal axis in as little as 2 weeks.

Cleaning and disinfecting the skin before surgery in a neonate requires special attention to the selection of agent, surface area affected, and the length of skin contact. For C.B., a 10% povidone–iodine solution should be gently applied to the penis and surrounding skin immediately before surgery and removed as soon as the 5- to 10-minute circumcision has been completed to minimize the risk for systemic toxicity resulting from enhanced percutaneous iodine absorption.

Case 102-3, Question 3: Are transdermal anesthetics an appropriate option for use before C.B.'s procedure?

Both 4% lidocaine and eutectic mixture of local anesthetics (EMLA) cream, which contain lidocaine and prilocaine, are widely used as topical anesthetics for infants and children before venipuncture, IV catheter placement, or circumcision. Both have been shown in clinical trials to be safe and effective.[16] The low concentration of the active ingredients and the limited duration of contact, 30 to 60 minutes, prevent excessive systemic absorption when applied to intact skin. Either analgesic cream would be appropriate for C.B. EMLA should be applied an hour before the start of the circumcision, whereas 4% lidocaine cream should be applied 30 minutes before the procedure. A thin layer of cream should be applied, without an occlusive dressing, and the baby diapered until

the start of the procedure. The cream should be completely removed before the application of the 10% povidone–iodine solution.

Other transdermal medications should be avoided or used with caution for only limited periods in infants. After the first year of life, transdermal application becomes a more useful route of administration for several medications. Methylphenidate and clonidine patches are used in the treatment of attention-deficit hyperactivity disorder (ADHD) in school-aged children, and both lidocaine and fentanyl patches are used for the treatment of older children and adolescents with severe pain.

RECTAL DRUG ABSORPTION

Case 102-3, Question 4: A week after C.B.'s discharge from the hospital, he is brought into the emergency department after becoming lethargic and febrile at home. His parents have tried giving him oral acetaminophen, but he is vomiting and unable to take liquids. Is rectal administration of acetaminophen an acceptable option for C.B. in the hospital after he has been stabilized?

Rectal administration is a useful route of drug delivery for many pediatric patients. Most drugs are well absorbed by this route, but the strong rectal contractions in infants can result in an inability to retain suppositories for the length of time needed to achieve optimal absorption.[7,8] Gels and liquid dosage preparations that do not require an extended time for dissolution are better options. Rectal diazepam gel is often used by parents of children with seizure disorders to provide rapid control of worsening seizures while awaiting emergency medical personnel. In an observational trial of 358 children, the median time from administration of rectal diazepam by a parent to cessation of seizures was 4.3 minutes.[17]

Rectal acetaminophen would be a viable option for C.B. It is rapidly absorbed through this route. Many drug dosing references recommend a slightly higher rectal acetaminophen dose (10–20 mg/kg) to account for a potentially lower bioavailability.

Drug Distribution

Growth and development also affect drug distribution. Organ size, body water content, fat stores, plasma protein concentrations, acid–base balance, cardiac output, and tissue perfusion all change throughout childhood, altering the pattern of distribution and extent of drug penetration.[7] The greatest degree of change occurs during the first year of life.

Case 102-3, Question 5: In the emergency department, C.B. is refusing to breast-feed and is having difficulty breathing. Neonatal sepsis with possible meningitis is suspected. Laboratory values and vital signs include the following:

Temperature, 102.92 °F (39.4 °C)
Heart rate, 202 beats/minute (normal 107–182 beats/minute)
Blood pressure, 85/62 mm Hg (normal systolic 70–75 mm Hg, diastolic 50–55 mm Hg)

He currently weighs 7.50 pounds (3.4 kg) and appears slightly dehydrated. His parents report that C.B. has had fewer wet diapers than usual during the last 24 hours. What physiologic differences in the neonatal period would affect your choice of empiric antibiotics for the treatment of neonatal central nervous system infections? What drugs would you select and what doses would you recommend?

Empiric antibiotic therapy for sepsis and meningitis for C.B. typically consists of ampicillin and aminoglycoside. Although not commonly used in adults because of the relatively low degree of penetration across the blood–brain barrier, this combination is very effective in the neonatal period when drug distribution into the central nervous system is higher. Constituting only 2% of total body weight in an adult, the brain makes up 10% to 12% of the weight of an infant. As a result, the brain serves as a much larger potential compartment for drug distribution. In addition, the percentage of systemic blood flow that reaches the cerebral vasculature is greater. These factors, along with a potential for greater passive diffusion of drugs across the functionally immature blood–brain barrier, can result in higher drug concentrations within the central nervous system of infants compared with older children and adults.[7,8] This

can produce both benefit and risk to the infant. Drugs given to treat meningitis or seizures are more likely to achieve therapeutic concentrations within the central nervous system, but there is also a greater potential risk for drug-induced neurotoxicity.

BODY WATER

One of the most significant differences in drug distribution during childhood is the decrease in total body water content with increasing age. Approximately 85% of a premature newborn's weight and 70% to 80% of a term newborn's weight are body water, compared with only 60% to 65% in a 1-year-old.[7,8] After a year of age, the percentage declines from 50% to 60% and remains relatively constant. Extracellular water decreases in a similar manner, from 40% to 45% in the newborn to 20% to 25% by the end of the first year of life. Intracellular water content, however, remains relatively stable. These changes result in a much greater distribution of highly water-soluble drugs, such as the aminoglycosides or linezolid, and a reduced accumulation of highly lipid-soluble drugs, such as amphotericin, amiodarone, benzodiazepines, or digoxin.

The pharmacokinetic profile of gentamicin has been well described in infants and children as a result of its role in empiric antibiotic therapy for neonatal sepsis and meningitis. The volume of distribution of gentamicin in premature neonates ranges from 0.5 to 0.7 L/kg, reflecting the higher extracellular water content at this age. This value falls to 0.4 L/kg by the end of the first year of life and further declines from 0.2 to 0.3 L/kg by adulthood.[18] As a result of their higher volume of distribution, the weight-based dose for an infant is often much higher than a comparable dose in an adult. Based on C.B.'s age and weight, the *Pediatric Dosage Handbook*,[18] one of the most widely used pediatric drug references, recommends an ampicillin dose of 255 mg (75 mg/kg) given IV every 6 hours (300 mg/kg/24 hour) and a gentamicin dose of 13.6 mg (4 mg/kg) given IV every 24 hours. Using these same weight-based doses in a 154.32-pound (70-kg) adult would result in doses much higher than the typical recommended adult dose.

BODY FAT

Whereas the effects of growth and development on changes in body water content are well defined and typically require adjustments in drug dosing only during infancy, the effects of changes in body fat are not yet well understood. Body fat increases throughout gestation and infancy. A premature neonate may have as little as 1% to 2% body fat, whereas a term infant will have closer to 10% to 15% body fat. A 1-year-old will have a body fat of 20% to 25%, similar to that of an adult. Children following normal growth patterns have relatively little change in their body fat percentage between the second year of life and the onset of puberty. However, the increasing rate of childhood obesity has generated concern about the efficacy and safety of current weight-based dosing strategies.[19] In a 2010 retrospective study of 699 children between ages 5 and 12 years admitted to a children's hospital during a 6-month period, overweight children (defined as having a body mass index >85th percentile for age) accounted for 33% of the admissions.[20] Evaluation of their medication orders revealed that 8.5% of the doses ordered were for less than the recommended dose, whereas 2.8% were for an excessive dose. The need to make dosage adjustments in these children remains controversial; only limited research is available documenting the effects of childhood obesity on the pharmacokinetics and pharmacodynamics of commonly used pediatric medications.

PROTEIN BINDING

Case 102-3, Question 6: On the third day of admission, the microbiology laboratory reports the culture and sensitivity results for C.B. Although the cerebrospinal fluid and urine cultures were negative, the peripheral blood culture grew *Escherichia coli*. The organism appears to be sensitive to a wide range of antibiotics, including penicillins, cephalosporins, gentamicin, and sulfamethoxazole-trimethoprim. What would your recommendation be for C.B.'s continuing treatment?

Many of the drugs that would treat C.B.'s infection are highly protein bound. Plasma protein binding is reduced in neonates as a result of decreased circulating levels of both albumin and α_1-acid glycoprotein, as well as decreased binding affinity.[7,8,12] With the known susceptibilities and their long history of efficacy and safety, continuing C.B.'s current ampicillin and gentamicin regimen for 7 to 10 days would be an appropriate choice. Although ampicillin is known to be present in higher unbound concentrations in infants compared with adults (**Table 102-2**), use of standard dosing recommendations for C.B. based on age should be adequate to prevent toxicity. Sulfamethoxazole-trimethoprim would not be appropriate. Administration of drugs with a high binding affinity for albumin, such as the sulfonamides, during the neonatal period can result in competition with bilirubin for binding sites. The resulting increase in unbound bilirubin can lead to kernicterus, neurologic damage caused by deposition of bilirubin in the brain, primarily in the basal ganglia.[21] For this reason, sulfonamides are not recommended for neonates and are not approved by the FDA for use in infants younger than age 2 months. Ceftriaxone, another possible option for C.B., also is known to be highly protein bound. Although approved for use in neonates, it is contraindicated in those with hyperbilirubinemia. As a precaution, many hospitals restrict its use in the neonatal population to only those patients who have infections resistant to other antibiotics.

Table 102-2

Examples of Drugs Present in Greater Unbound Concentrations in Neonates Than in Adults

Alfentanil	Penicillin G
Ampicillin	Phenobarbital
Ceftriaxone	Phenytoin
Cefuroxime	Propranolol
Diazepam	Salicylates
Digoxin	Sulfonamides

Alfentanil	Penicillin G
Lidocaine	Theophylline
Ketamine	Valproic acid
Morphine	
Nafcillin	

The clinical impact of changes in protein binding can be difficult to predict. Separation and measurement of the unbound (free) fraction can be used to guide therapy for drugs such as valproic acid or phenytoin, but this process is more labor-intensive and expensive and, as a result, may not be available at all hospitals. Larger blood sample volumes may also be required, which can lead to excessive blood loss in premature infants. An estimation of the unbound concentration can be made from total serum drug concentrations but may not be accurate in infants. Methods to estimate unbound serum valproic acid concentrations from total concentrations that were developed for adults have been found to be ineffective in predicting free levels in neonates and infants.[22]

Metabolism

Much of the research currently being conducted in developmental pharmacology is focused on changes in metabolic function.[7,8,12,23–50] Our understanding of the ontogeny of metabolic enzymes is improving rapidly, because in vitro data gathered from studies quantifying hepatic microsomal proteins and determining levels of enzymatic activity are combined with information obtained through pharmacokinetic and pharmacogenomic research. It is clear that the onset of function varies among enzymes; whereas some exhibit metabolic activity in utero, others demonstrate activity only after several months of life. The development of metabolic enzyme function continues during the first years of life and does not appear to be complete until after puberty. There appears to be considerable interpatient variability. Enzyme development can be affected by the

underlying health of the child, nutritional status, and exposure to substrate. Metabolic activity also reflects genetic polymorphisms, just as in adults.

PHASE I DRUG METABOLISM

CASE 102-4

QUESTION 1: N.M. is a 3.04-pound (1.38-kg), 3-week-old female who was born at 28 weeks' gestational age. She has recently been started on nasogastric feedings but has had repeated episodes of emesis and is not producing regular stools. Erythromycin is recommended to increase her gastric motility.

What can you tell your team about the ability of N.M. to metabolize this drug? What dose of erythromycin would you recommend for N.M.?

Phase I reactions, which include oxidation, reduction, hydroxylation, and hydrolysis, develop at varying rates during childhood, resulting in the wide range of half-lives reported for many drugs. The cytochrome P-450 (CYP) 3A enzymes, which play a major role in drug metabolism, including that of erythromycin, develop early in life.[7,8,12,23–28] The earliest isozyme in this group to show activity is CYP3A7, the primary metabolic enzyme present in utero. It has been found on the endoplasmic reticulum of fetal hepatocytes by the end of the first trimester and serves a role in the transformation of fetal dehydroepiandrosterone and the detoxification of retinoic acid derivatives transferred from maternal serum across the placenta.[23,24,26–28] Enzymatic activity of CYP3A7 declines rapidly after birth, with a 50% reduction during the first month of life. Levels continue to decline at a slower rate through the next 6 months and are typically undetectable after age 1 year. As levels of CYP3A7 decline, CYP3A4 and CYP3A5 levels rise. Although present during fetal development, the level of CYP3A4 activity is nearly 100-fold less than that of CYP3A7 until after birth.[23,28] Increases in CYP3A4 occur over the first months of life, often reaching levels of enzymatic activity higher than that seen in adults during early childhood.

Development of CYP3A5 function is highly variable among infants and children and does not appear to be related to patient age.

It can be anticipated that N.M. will have a slower rate of erythromycin metabolism as a result of lower levels of CYP3A4 activity, so a more conservative approach to dosing is often used. An oral erythromycin dose of 7 mg (5 mg/kg) given every 8 hours would be an appropriate starting dose for N.M. In addition to increasing the risk for adverse effects, higher serum erythromycin concentrations can lead to greater inhibition of CYP3A4. This may place N.M. at risk for toxicity from accumulation of other drugs metabolized via CYP3A4, such as fentanyl and midazolam.

Upregulation of CYP2D6 appears to begin in the last stage of gestation as a part of the complex transition of the baby to extrauterine life.[23–25,29] In fetal liver tissue samples obtained early in gestation, CYP2D6 activity has been reported to be only 1% to 5% of adult values.[23] Earlier studies suggested that levels of enzymatic activity remained low during infancy, but more recent research has demonstrated that CYP2D6 activity increases rapidly during the third trimester, and by the second week of life, values are similar to values in adults.[24] CYP2D6 levels remain relatively constant throughout childhood. The impact of genetic polymorphisms of CYP2D6 on elimination half-life in children is comparable to that demonstrated in adults and appears to play a greater role in determining metabolic function than ontogeny.[24,25,27] A study of atomoxetine response in children and adolescents with ADHD found that CYP2D6-poor metabolizers had greater increases in heart rate and blood pressure and impaired weight gain compared with extensive metabolizers taking comparable doses, reflecting higher serum concentrations with the poor metabolizer phenotype.[30]

The enzymatic activity of CYP2C9 and CYP2C19 develops throughout childhood.[23,24,31] Studies of fetal hepatocytes demonstrated CYP2C9 activity at only 1% of adult values from 8 to 24 weeks' gestation, with an increase from 10% to 20% between 25 and 40 weeks. Enzyme activity continues to increase after birth, reaching 25% of adult values by approximately age 5 months. Unlike other enzymes, CYP2C9 activity remains at only 50% of adult values

until after puberty. The development of CYP2C9 activity is illustrated by the change in the rate of metabolism of phenytoin with advancing age. The apparent (calculated Michaelis–Menten) half-life of phenytoin in premature infants is ~75 hours, compared with 20 hours in a term neonate and 8 hours in a 2-week-old.[32]

Development of CYP2C19 function also occurs in utero, with enzyme activity 10% to 20% that of adults at birth.[24] Enzymatic activity increases gradually during the first 3 months of life to near-full adult values. As with CYP2D6, genetic polymorphisms for CYP2C9 and CYP2C19 play an important role in determining individual patient response. Population modeling of pantoprazole pharmacokinetics in term neonates and premature infants revealed a longer elimination half-life than that reported in adults, supporting the lower levels of CYP2C19 activity in this age group.[33] The study also demonstrated significantly greater drug concentrations in the patients who had the poor metabolizer genotype.

The ontogeny of CYP2E1 has been studied in conjunction with the ability of infants to metabolize acetaminophen. Fetal hepatic CYP2E1 concentrations are typically undetectable during the first trimester, but begin to increase during the second trimester.[34] Levels are ~10% to 20% of adult values at birth. Enzyme concentrations continue to increase at a more gradual pace, until by age 3 months, CYP2E1 expression becomes similar to that in adults. The increase in CYP2E1 metabolic capacity, along with maturation of glucuronidation, is responsible for the changing patterns of acetaminophen metabolite formation during infancy.

Case 102-4, Question 2: N.M. is now tolerating her enteral feedings and was recently extubated. However, she has had increasing episodes of apnea, a pause in breathing of 20 seconds or greater frequently present in premature newborns, during the past 2 days. Based on current dosing guidelines, you have recommended a caffeine citrate loading dose of 20 mg/kg given IV to be followed by a maintenance dose of 5 mg/kg given once daily to treat her apnea.[35] While reviewing the dosing information, you note that the elimination half-life for caffeine in neonates is ~70 to 100 hours, whereas the half-life for older infants, children, and adults is only 5 hours. What would explain that dramatic difference in half-life?

The changing elimination half-life of caffeine reflects the onset and maturation of CYP1A2 activity. The metabolism of caffeine during infancy has been extensively studied because many neonates are exposed in utero as a result of maternal intake, and premature infants often receive caffeine for the treatment of apnea.[23,24,35,36] Studies have shown that CYP1A2 activity is negligible in fetal liver tissue and in newborns who were not exposed to it in utero.[36] The lower levels of enzymatic activity result in a longer caffeine half-life and allow once-daily dosing.[37] In contrast, newborns exposed to caffeine during gestation have higher levels of CYP1A2 activity at birth. Enzymatic activity rises progressively during the first months of life. By age 6 months, it may exceed adult values, giving the infant a caffeine half-life of only 4 to 5 hours and necessitating more frequent dosing.

Case 102-4, Question 3: While N.M. was receiving mechanical ventilation during her first weeks of life, she was sedated with an infusion of midazolam. Many IV products, including some brands of midazolam, contain benzyl alcohol as a preservative and are labeled "Not for Use in Infants." What is the rationale for restricting the use of benzyl alcohol in the neonatal population?

Alcohol dehydrogenase, another phase I enzyme, is present in utero, but in concentrations <5% of adult values.[24] Enzymatic activity does not approach functional maturity until approximately age 5 years. The lack of alcohol dehydrogenase activity has a profound impact on the ability of newborns to metabolize benzyl alcohol, a common preservative in injectable drug products. In 1982, five neonates died after developing gasping respirations that progressed to respiratory failure, severe metabolic acidosis, renal and hepatic failure, thrombocytopenia, and cardiovascular collapse.[38] All of the infants had been repeatedly exposed to benzyl alcohol as a preservative in IV flush solutions. This toxicity, termed *gasping syndrome*, resulted from accumulation of the parent compound, as well as the benzoic acid metabolite. Another series of ten patient deaths was reported from a second institution.[39] From these case series, the threshold for toxicity was estimated to be a total daily

exposure of 99 mg/kg/day. Within months of these reports, the FDA issued a safety alert calling attention to this reaction and recommending use of preservative-free products or preparations with alternative preservatives in newborns.[40] This change in practice led to the virtual elimination of gasping syndrome and brought to light the significance of differences in neonatal metabolism on drug toxicity. Pediatric clinicians continue to be vigilant for benzyl alcohol exposure, because several drugs routinely used in premature and critically ill neonates are not available in preservative-free preparations.[41]

PHASE II DRUG METABOLISM

Phase II reactions, including glucuronidation, sulfation, and acetylation, also undergo change throughout childhood. Present in low levels in fetal hepatic and renal tissues, the uridine 5′-diphosphate glucuronosyltransferase (UGT) enzymes responsible for the glucuronidation of both drugs and endogenous substances have minimal metabolic activity. A gradual increase in UGT expression occurs in the first 6 months of life, but still remains lower than that of adults for the first 2 to 3 years of life. Genetic polymorphisms produce additional variation in UGT expression.[12,23,24,42–45] The reduced ability of infants to perform glucuronidation has been known for many years as a result of the chloramphenicol "gray baby syndrome." Chloramphenicol was a widely used antibiotic during the 1950s. Within several years of its introduction, case reports began to appear in the medical literature describing emesis, abdominal distension, and cyanosis followed by cardiovascular collapse in infants given the drug.[47] The mechanism for this toxic effect was later found to be reduced activity of UGT2B7, the primary enzyme responsible for chloramphenicol metabolism, that allowed accumulation of the parent compound.[24,42]

Case 102-4, Question 4: N.M. also received morphine as an infusion during mechanical ventilation. Careful attention is needed when administering opioids to neonates to avoid drug accumulation. What differences in metabolism might

affect the dosing requirements of morphine in the premature neonate such as N.M.?

Glucuronidation of morphine to morphine-6-glucuronide and morphine-3-glucuronide via UGT2B7 can be demonstrated in premature neonates born as early as 24 weeks' gestational age, but at a much slower rate than that of term neonates.[24,44,48,49] Studies of fetal liver microsomes have confirmed the presence of UGT2B7, with a rate of enzymatic activity only 10% to 20% of adult values.[23] Morphine metabolism increases rapidly during the last trimester of intrauterine life and the first weeks after birth. Clearance has been estimated to increase fourfold between 24 and 40 weeks' postconceptional age, but remains substantially slower than that of adults until approximately age 3 years.[48,49]

Sulfation is a more important pathway in the metabolism of morphine during early infancy than later in life. Unlike UGT enzymes, sulfotransferases (SULTs) develop extensively in utero, reaching levels of enzyme activity similar to that of adults at birth.[23,24,50] Intrauterine expression of SULT1A1, which is responsible for fetal metabolism of thyroid hormones, SULT2A1, the enzyme that metabolizes steroid hormones, and SULT1A3, which metabolizes catecholamines, occurs early in gestation and remains relatively constant thereafter. Not all SULT enzyme development takes place in the liver. Expression of SULT2A1 occurs primarily in the fetal adrenal gland.

The reliance on sulfation during infancy is found with several drugs besides morphine, including catecholamines, thyroid hormones, theophylline, and acetaminophen. Glucuronidation of acetaminophen via UGT1A6 and UGT1A9 is decreased in infants, and as a result, the primary route of acetaminophen metabolism is the formation of sulfate conjugates for the first year of life.[24,46] Glucuronide pathways begin to predominate later in infancy and eventually surpass sulfation as the predominate route for acetaminophen metabolism.

Because of the slower rate of morphine clearance in neonates, particularly those born prematurely, morphine should be initiated at lower doses than those recommended for older infants and children.

An appropriate starting dose for N.M.'s morphine infusion would be 0.010 to 0.015 mg/kg/hour. N.M. should be closely monitored for adverse effects, including hypotension, respiratory depression after extubation, and constipation.

Elimination

CASE 102-5

QUESTION 1: E.C. is a 4.08-pound (1.85-kg) female born at 30 weeks' gestation. As with the other neonates described earlier, she is started on empiric antibiotic therapy with ampicillin and gentamicin shortly after birth. E.C. is given ampicillin 185 mg (100 mg/kg) IV every 8 hours and gentamicin 8.3 mg (4.5 mg/kg) IV every 36 hours. In the next bed, N.M., now 2 months old (36 weeks' corrected gestational age [GA]) and 5.73 pounds (2.6 kg), is on the same regimen for a fever and elevated white blood cell count during the past 24 hours. N.M. is given ampicillin 130 mg (50 mg/kg) IV every 6 hours and gentamicin 10.4 mg (4 mg/kg) IV every 24 hours.

What is the rationale for the differences in these patients' dosing intervals?

GLOMERULAR FILTRATION

Like the liver, the kidneys are not fully developed at birth. The ability to filter, excrete, and reabsorb substances is not maximized until age 1 year.[7,8,51,52] At birth, full-term neonates have an average glomerular filtration rate (GFR) of only 2 to 4 mL/minute/1.73 m^2; in premature infants, the value may be even lower (0.6–0.8 mL/minute/1.73 m^2). There is a rapid rise in GFR during the first 2 weeks of life, with values increasing from 20 to 40 mL/minute/1.73 m^2 as a result of increased renal blood flow, increased function of the existing nephrons, and the appearance of additional nephrons, all of which may be timed to coincide with birth.[52] GFR increases from 80 to 110 mL/minute/1.73 m^2 by 6 months of age and continues to increase in a linear manner until it approaches adult values of 100 to 120 mL/minute/1.73 m^2 by age 1 year. The impact of this increase in GFR can be seen in the neonatal dosing recommendations for many renally eliminated drugs, including the aminoglycosides and

vancomycin. To account for reduced renal function, most pediatric references use a combination of patient weight and age (postnatal, postconceptional, or postmenstrual) to determine gentamicin dosing in neonates.[18] As a premature newborn, E.C. is likely to have an increased volume of distribution (V_d) of gentamicin but significantly reduced glomerular filtration. E.C.'s gentamicin regimen will consist of a larger neonatal dose to account for the V_d (4.5 mg/kg) given at a less frequent interval 36 hours than that of 2-month-old N.M. to compensate for her renal insufficiency.

TUBULAR SECRETION

The elimination of ampicillin is also affected by changes in the rate of tubular secretion.[7,8,51] Like GFR, tubular secretion is reduced immediately after birth, but gradually increases during the first year of life. In addition to the penicillins, a reduction in tubular secretion results in a prolonged elimination half-life for cephalosporins, furosemide, and digoxin. Digoxin has been used for many years in the management of supraventricular tachycardia in neonates. The half-life of digoxin decreases from ~30–40 hours in a term neonate to 20–25 hours in a 1-year-old as renal function matures. Selection of a digoxin dose must take into account the difference in elimination. The recommended oral digoxin maintenance dose for a neonate is 5 µg/kg/day, whereas a 2-year-old would need to receive twice that amount to achieve target serum digoxin concentrations.[53] Ampicillin doses are typically adjusted by lengthening the dosing interval to compensate for reduced tubular secretion. E.C. (a newborn delivered at 30 weeks' gestation) would be dosed every 8 hours, whereas an older child such as N.M. would be expected to clear ampicillin more rapidly and would be dosed every 6 hours.

CASE 102-5, QUESTION 2: How should renal function be assessed in E.C. and N.M.?

As with adults, renal function should be closely monitored in children and drug doses adjusted accordingly. Unlike adults, blood

urea nitrogen and serum creatinine values are not always useful as indicators of renal function. In the first days after birth, serum creatinine values reflect maternal creatinine transferred through the placenta and may appear falsely elevated. After the first week, serum creatinine values are typically low as a result of less muscle mass, especially in premature neonates, and may not accurately represent renal function.[8] Urine output is often used as an additional measure of renal function in this population. Diaper weights can be used to estimate output in E.C. and N.M., with values >1 mL/kg/hour considered adequate renal function. At the time of initiation of therapy, if both babies are maintaining urine output values >1 mL/kg/hour, the dosing regimens recommended in the *Pediatric Dosage Handbook*[18] can be used without further alteration. If urine output falls, the dosing intervals of both antibiotics may require adjustment. A trough serum gentamicin concentration should be obtained to further guide dosing.

CASE 102-6

QUESTION 1: H.G. is a 10-year-old male admitted with osteomyelitis in his left ankle. The team plans to treat H.G. with vancomycin for 6 weeks. He is 55.11 inches (140 cm) tall and weighs 70.55 pounds (32 kg). His serum creatinine is 0.5 mg/dL (normal for age 0.5–1.0 mg/dL).

What is H.G.'s creatinine clearance?

After infancy, serum creatinine may be used to estimate clearance. The equations used in adults, such as Cockroft–Gault, Jelliffe, or the Modification of Diet in Renal Disease (MDRD), are not appropriate for patients younger than age 18 years.[8,54,55] There are several equations designed for pediatric use; the National Kidney Disease Education Program (NKDEP) and the National Kidney Foundation recommend the bedside isotope dilution mass spectroscopy (IDMS) Schwartz equation[54]:

$$CL_{Cr} = (0.14 \times Ht) / S_{Cr} \qquad \text{(Eq. 102-1)}$$

where CL_{Cr} is creatinine clearance (mL/minute/1.73 m^2), Ht is height (cm), and S_{Cr} is serum creatinine (mg/dL).

Using this method, H.G. has a calculated creatinine clearance of 116 mL/minute/1.73 m^2, indicating normal renal function. As with patients of any age, this equation should be used only as an estimate of renal function. It should be interpreted with caution in patients with little muscle mass or those who are dehydrated.

Pharmacokinetic Changes During Puberty

CASE 102-7

QUESTION 1: A.M. is a 16-year-old, 147.71-pound (67-kg) male with osteosarcoma. He has received morphine for pain throughout his numerous hospitalizations for surgery and chemotherapy during the past 2 years, requiring an infusion rate as high as 0.5 mg/kg/hour. During this period, he has also progressed through puberty and is now a mature adult male. During his last admission, it was noted that his pain was well controlled on an adult morphine infusion rate of 10 mg/hour, equivalent to 0.15 mg/kg/hour. It was noted by the medical team that A.M.'s morphine infusion requirements were actually lower than in earlier admissions, although his pain scores have been unchanged.

What might explain the change in A.M.'s response to morphine?

Although developmental pharmacology has traditionally focused on the differences in neonatal pharmacokinetics, there is growing interest in the influence of puberty on drug disposition.[56–58] Adolescence is not simply a link between childhood and adulthood, but is a distinct period of significant physiologic change. Hormonal fluctuations and sexual maturation can alter the efficacy or toxicity of many drugs administered during this period. Drug distribution can be altered as a result of an increase in body fat. Rapid increases in serum protein concentrations that occur during puberty alter drug-binding characteristics.[57] Renal function, as measured by GFR, may exceed average adult values, resulting in rapid clearance of renally eliminated drugs such as aminoglycosides and vancomycin. Metabolic activity changes as well.[58] A study conducted in

adolescents receiving morphine during a sickle cell crisis revealed a reduction in drug clearance with advancing sexual maturation.[59] Postpubertal adolescents, such as A.M., had weight-normalized clearance values 30% lower than younger patients during early puberty, suggesting a possible reduction in UGT2B7 activity. The titration of A.M.'s morphine must encompass not only the changes in drug clearance resulting from growth and development but also the progression of his disease and his need for pain control. Assessment of pain, using frequent self-report or a standardized pain scale, as well as heart rate, blood pressure, and respiratory rate, is essential for appropriate adjustment of A.M.'s morphine infusion.

A second example comes from a recent study of lopinavir pharmacokinetics in children who exhibited identified age- and sex-related differences in drug clearance.[60] When normalized for weight, there was no significant difference in clearance between prepubertal boys and girls. After age 12 years, males had a mean rate of lopinavir clearance 39% greater than females. The area under the concentration–time curve in boys was only half that of the girls. The authors suggest that this difference may reflect a reduction in CYP3A4 in girls that becomes apparent only with sexual maturation. Similar sex-related results have been reported in lopinavir studies conducted in adults. Caffeine metabolism via CYP1A2 has also been found to differ by sex in adolescents.[61] The rate of *N*-demethylation slows in both sexes after puberty, but appears to decrease earlier in puberty for females than for males. Other investigators have identified pharmacokinetic changes during adolescence with acetaminophen, alprazolam, carbamazepine, digoxin, isoniazid, lamotrigine, lorazepam, and theophylline.[57]

PEDIATRIC PHARMACODYNAMIC DIFFERENCES

Although not as well studied as pharmacokinetics, developmental changes in pharmacodynamics during growth may have equally significant effects on response to drug therapy in children.

CASE 102-8

QUESTION 1: S.L. is a 1.60-pound (0.725-kg) male with an estimated gestational age of 24 weeks. He was brought to the neonatal intensive care unit immediately after birth with severe hypotension. A dopamine infusion was started at a rate of 10 µg/kg/minute and quickly titrated to 20 µg/kg/minute without significant benefit.

What might explain S.L.'s lack of response, and how should his hypotension be managed?

Maturational changes in receptor conformation, density, and affinity, as well as signal transduction, can result in clinically significant differences in response to common therapies.[62] Although a dopamine infusion of 20 µg/kg/minute will produce an adequate increase in myocardial contractility and elevate systemic vascular resistance in most children and adults, infants may not have a significant change in cardiovascular response. Infants have long been suspected to be relatively resistant to the effects of β-adrenergic agonists, including dopamine, dobutamine, and epinephrine. Recent research suggests the lack of response is related to a relative reduction in adrenergic receptor density or a downregulation of receptors within the myocardium of premature and critically ill neonates.[63] A higher dopamine infusion rate, up to 40 µg/kg/minute, may be necessary to achieve an adequate blood pressure for S.L. If the dopamine is increased, S.L.'s extremities must be closely monitored for any signs of excessive peripheral vasoconstriction. Supplemental therapy with stress dose hydrocortisone, at a dose of 0.7 mg (1 mg/kg) IV every 8 hours, may also be used to manage his hypotension.

CASE 102-9

Question 1: You will be counseling the parents of E.S., a 7-year-old female with refractory seizures as a result of Lennox–Gastaut syndrome, on the use of lamotrigine. While preparing for your discussion, you notice in the manufacturer's prescribing information a black-box warning regarding the risk for serious skin rashes. The incidence is listed as 0.8% in children ages 2 to 16 years but only 0.3% in adults.[64]

What might explain the difference in the incidence of an adverse effect by age?

Differences in pharmacodynamics resulting from growth and development can alter more than just therapeutic response. A drug's adverse effect profile may be distinctly different during childhood. A classic example of this phenomenon is the higher incidence of serious dermatologic reactions, including toxic epidermal necrolysis, in children taking lamotrigine compared with that of adults.[65–67] This was first suspected during initial pediatric clinical trials and appeared to be associated with rapid dose titration during the first several months of treatment, which had been based on previous studies in adults.[66] The slower dose escalation, now recommended for pediatric patients, is starting E.S.'s lamotrigine dose at 0.15 mg/kg/day and increasing by 0.15- to 0.3-mg/kg/day increments every 2 weeks, and may reduce the likelihood for these reactions.

Case 102-9, Question 2: What is the possible mechanism(s) for the increased risk for toxicity with lamotrigine in children such as E.S.?

Research has led to several theories for the greater incidence of serious dermatologic reactions in children. Some investigators have suggested that this is a dose-related toxicity more evident in children who have a limited capacity to metabolize lamotrigine through glucuronidation to its inactive metabolites.[66] This theory, however, does not explain why other patient groups known to have higher serum lamotrigine concentrations during treatment, such as the elderly, are not at increased risk. Others have speculated that this represents an immune-mediated hypersensitivity response, because many of the affected patients reported have had previous reactions

with other antiepileptic drugs.[67] Children with refractory seizures, such as those with Lennox–Gastaut syndrome, who are often treated with multiple agents beginning in the first years of life may be more likely to develop hypersensitivity. Although the mechanism underlying the age-related difference in the incidence of lamotrigine-associated rashes is not yet well understood, the importance of patient counseling is clear. The caregivers of all children receiving lamotrigine should be made aware of the risk and the need to seek medical care as soon as any signs of rash or erythema are noted.

MEDICATION DOSING IN CHILDREN

CASE 102-10

QUESTION 1: A.K. is a 7-year-old, 44.09-pound (20-kg) male recently diagnosed with ADHD. After developing insomnia when treated with methylphenidate, he was switched to clonidine by his pediatrician. The recommended starting dose for clonidine in children is 5 µg/kg/day divided and given in two to four doses.[68] His prescription is for clonidine 0.05 mg by mouth twice daily. Because A.K. does not yet swallow tablets easily, he will need a solution made from the tablets. It will be prepared from a published extemporaneous formulation with a final concentration of 0.1 mg/mL.

What steps are necessary to ensure the accuracy of this prescription?

The differences in pharmacokinetics and pharmacodynamics observed in children influence the choice of dose and dosing interval.[69] Because incorporating all of these variables would result in dosing calculations too difficult for practical use, weight has traditionally been chosen as the single best estimate of growth. Pediatric drug references provide most doses in units per weight, such as mg/kg/day or µg/kg/dose. Among the exceptions to this are chemotherapeutic agents, which are dosed by body surface area, incorporating height as an additional variable. Because of the difficulty in accurately determining height (or length) in young children, it is not commonly used for other drugs.

Age can be an important variable, especially for premature infants, in whom it can be used to account for differences in volume of distribution and elimination half-life. For example, neonatal gentamicin dosing is often based on a rubric of gestational or postconceptional age, postnatal age, and weight.[18] A recent study of clonidine clearance in the early postnatal period suggests that both age and weight should be used to optimize clonidine doses in newborns being treated for neonatal abstinence syndrome.[70] In the future, pediatric dosing recommendations for many drugs may be based on more than just weight to incorporate new pharmacokinetic data.[71]

Medication orders or prescriptions with doses outside of the dosing range listed in a pediatric drug reference should always be questioned for appropriateness. Older children and adolescents should transition to adult dosing whenever the calculated weight-based dose exceeds the usual adult dose. When evaluating a pediatric prescription or medication order, determining whether the dose is appropriate for the patient's weight is not the only step undertaken by the pharmacist. As with all patients, allergies, underlying diseases, and concomitant therapy must be taken into account as well.

A.K.'s clonidine dose of 0.05 mg twice daily is equivalent to 5 µg/kg/day, the appropriate starting dose for a child. Using a 0.1-mg/mL extemporaneous solution, his dose will be 0.5 mL twice daily. The label on A.K.'s clonidine bottle should include the concentration of the formulation, as well as the dose in both mg and mL. Before the start of treatment, A.K.'s parents should be counseled about the drug, the dose, and potential adverse effects. They should be given or have access to an oral dosing syringe to accurately measure the dose.

PREVENTING MEDICATION ERRORS IN CHILDREN

Case 102-10, Question 2: After 2 days of therapy, A.K. returns to his pediatrician's office with his parents. He is lethargic and feels dizzy when getting out of bed. His blood pressure is 90/54 mm Hg (normal for age and weight is 99/59 mm Hg), suggesting a possible clonidine overdose. As you begin to investigate the potential cause of A.K.'s symptoms, what factors may have led to an error in A.K.'s case?

Medication errors pose a significant risk for infants and children.[72–76] Although the rate of medication errors reported in studies of adults is ~5%, rates in many pediatric studies have ranged from 10% to 15%.[72–74] The need to calculate weight-based doses can lead to mathematic errors. In A.K.'s case, the dose must be multiplied by the patient's weight, divided into individual doses, and converted from micrograms to milligrams. Unit conversions and decimal point errors are particularly dangerous in pediatrics, because a 10-fold overdose of a drug with a narrow dosing range such as clonidine, digoxin, morphine, or fentanyl can be fatal.[77] In addition to prescribing errors, dosage formulation manipulation, such as the preparation of an extemporaneous liquid in this case, increases the risk for drug preparation errors. Oral liquid medications also present a risk for administration errors. Health care providers and caregivers in the home must be aware of the potential for errors and the need for precise dose measurement. A.K.'s medical history must include information on how the clonidine had been prepared by the pharmacy as well as how his parents were preparing and administering his doses.

Case 102-10, Question 3: What steps could have been taken to prevent the medication error that occurred with A.K.?

There are a number of methods to reduce the potential for medication errors, including recommendations from the Joint Commission, the American Academy of Pediatrics, and a recent Cochrane review (**Table 102-3**).[75,76,78–83] Use of standard concentrations for IV products and oral liquids, smart-pump technology, bar coding, and electronic prescribing with clinical

decision support tools have been found to significantly reduce errors in pediatric hospitals. In the outpatient setting, medication errors can be reduced by the inclusion of patient-specific information on prescriptions, including diagnosis and patient weight.[84] The product label, whether it is a prescription or over-the-counter medication, should include all the information needed to correctly prepare and administer the dose. Caregivers should have access to the appropriate tools for measuring liquid medications, such as oral dosing syringes, and the opportunity to practice preparing a dose under the supervision of a health care provider to ensure that they are able to prepare the dose correctly.[85]

Table 102-3

Methods for Reducing Pediatric Medication Errors

Improve Ordering and Preparation
Perform careful medication histories, including assessment of oral liquid concentrations
Provide access to current pediatric medication information
Include patient weight (in kg) on all medication orders and prescriptions
Include dosage calculations on orders and prescriptions
Limit the number of concentrations available for high-risk medications
Use accurate measuring devices in both the hospital and home settings
Implement Appropriate Technology
Adopt weight-based electronic prescribing or dose-checking software
Employ barcode technology to reduce patient identification and medication administration errors
Use smart-pump technology (programmable IV pumps with weight-based dosing limits)
Use Staff Expertise
Provide pediatric-specific continuing education for all staff on a routine basis
Develop pediatric-specific medication orders and protocols to guide care
Assign staff with pediatric expertise to all committees involved in medication management

Improve Ordering and Preparation
Involve Families and Other Caregivers
Encourage all caregivers to ask questions about their child's medications
Recommend that all caregivers know the names and doses of their children's medications or carry information about their medications
Remind caregivers to include nutritional supplements, herbal or complementary therapies, and over-the-counter medications when giving a medication history
Ensure that caregivers can accurately prepare the medication dose

IV, intravenous.

One of the most effective methods to prevent medication errors has been to include pharmacists in the medication ordering and review process.[84,86] The value of pharmacists in reducing pediatric medication errors was demonstrated by Folli et al.[86] In this landmark study, clinical pharmacists performed prospective evaluations of medication orders at two children's hospitals for a 6-month period. The overall rate of medication errors detected by the pharmacists averaged 4.7 per 1000 medication orders. Of these, 5.6% were considered potentially lethal. The majority of the errors (64.3%) occurred in children younger than age 2 years. The most common type of error identified by the pharmacists was incorrect dosage. The authors concluded that pharmacy intervention had a significant effect on medication error prevention, a finding that resulted in the expansion of pediatric clinical pharmacy services in many institutions. Pharmacists in the community provide the same benefit when reviewing pediatric prescriptions and play a significant role in caregiver medication education.

The National Health and Nutrition Examination Survey (NHANES) is a program of studies designed to assess the health and nutritional status of adults and children in the United States. Qato and colleagues[87] conducted a descriptive analysis of prescription data collected from 2009 to 2014. They found that 8.2% of children receiving two or more medications (N = 301) were at risk of a major drug–drug interaction when their medications were entered into a drug interaction database. This demonstrated the need for

pharmacist to perform a comprehensive medication review for patients when new medications are added into their regimen.

INCREASING AVAILABILITY OF PEDIATRIC MEDICATION INFORMATION

Case 102-10, Question 4: Although the dose of clonidine for the treatment of ADHD is available in most pediatric dosing references, it is not found in the manufacturer's prescribing information (package insert) for the drug because the treatment of ADHD is not currently an FDA-approved indication. What is being done to increase the availability of pediatric drug information?

Although the availability of pediatric drug information has been limited in the past, several recent initiatives from the FDA are increasing the number of clinical trials being conducted in infants and children. The Pediatric Exclusivity Program, part of the FDA Modernization Act of 1997, was developed to address the lack of pediatric study data, including medication prescribing information.[8,88–90] The Exclusivity Program provides pharmaceutical manufacturers with incentives to study their products in children, including a 6-month extension at the end of a drug's patent life if a pediatric study is conducted. The 1998 Pediatric Rule and the Research Equity Act of 2003 authorized the FDA to require that manufacturers conduct clinical trials of drugs that would be used in a significant number of patients. The Best Pharmaceuticals for Children Act supplements the previous incentives by the creation of a mechanism for funding studies of older, off-patent medications that are often used in children.

These programs have been successful in adding pediatric dosing and adverse effect information to the prescribing information of many drugs routinely used in children. As of June 2021, the FDA had issues 520 written request for pediatric studies, and greater than 250 drugs had been granted a patent extension under the exclusivity Program. An assessment of the first 7 years of the program found

that 50% of the studies conducted resulted in the new information supporting the use of the drug in children.[87] In spite of this success, much work remains to be done. Modifications in clinical trial design to incorporate pharmacogenomic studies and the use of combined pharmacokinetic–pharmacodynamic analyses have been recommended to further refine our knowledge of drug disposition in children.[89,90] The emphasis on the needs of pediatric patients has not been limited to just the United States; similar programs are in place in the European Union and throughout Asia. With the growing interest in developmental pharmacology and pharmacogenomics, as well as the increased funding and support for pediatric clinical trials worldwide, our understanding of the unique differences in how children respond to drug therapy continues to improve.

Pediatric Fluid, Electrolytes, and Nutrition

Jennifer W. Chow and Lisa M. Feagin

CORE PRINCIPLES		CHAPTER CASES
1	Fluid requirements and calories normalized to body weight are much greater in very small children than in older children and adults. It is important to understand how to calculate the normal fluid and caloric needs of children, and how these needs vary with changes in clinical status.	**Case 103-1 (Question 1)** **Case 103-2 (Question 1–3)** **Case 103-3 (Question 1–3), Tables 103-1–103-5**
2	Human milk is the ideal food for a human infant. In addition to meeting the infant's nutritional requirements, human milk provides the infant with protection against a wide variety of infectious diseases and noninfectious disorders. Solid foods are generally introduced at 4	**Case 103-4 (Questions 1, 2, 4, 5)**

	to 6 months of age and cow's milk after 1 year.	
3	Infant formula is available in three different formulations: cow's milk-based, soy-based, and protein hydrolysate (elemental). Cow's milk-based formulas are standard for most infants. Soy-based and protein hydrolysate formulas are primarily intended for infants intolerant to cow's milk-based formulas. Other therapeutic formulas are available for infants with disease states that preclude the use of one of these three main types of formula.	**Case 103-4 (Question 3)** **Case 103-5 (Question 1)** **Case 103-6 (Question 2, 3)**
4	Growth assessment is an important focus of pediatric health care, especially during the first year of life. With the exception of the intrauterine period, the most rapid growth occurs during the first year.	**Case 103-6 (Question 1)**
5	Parenteral nutrition (PN) in infants and children is usually initiated below estimated caloric needs and advanced as tolerated over 3 or more days until goal caloric needs are met.	**Case 103-6 (Question 4)**
6	PN can be used to supply sufficient nutrients to promote healing and a normal growth rate in sick infants and children. However, PN is associated with clinically significant risks and complications.	**Case 103-7 (Questions 1–5, 7–9), Table 103-5**
7	Specialized pediatric amino acid	**Case 103-7 (Question**

	solutions are available for infants younger than 1 year of age. These products were designed to produce plasma amino acid patterns closely matching those of human milk-fed infants.	**6)**
8	Irreversible liver damage can occur with long-term PN. PN-associated liver disease usually presents as an elevated direct (conjugated) bilirubin level and can occur as early as 2 weeks after beginning PN.	**Case 103-7 (Question 10, 11)**
9	A number of modifications can be made to the patient's PN regimen to alleviate or slow the progression of cholestasis. The initiation of enteral feeding, even if limited to low-volume trophic feeding, appears to be the most effective method for prevention.	**Case 103-7 (Question 11)**

INTRODUCTION

Adequate nutrition is an essential component of the health maintenance of children and, in part, has dramatically reduced infant mortality seen in the United States during the 20th century. Clinical experience has confirmed the value of optimal nutrition in resisting the effects of disease and trauma and in improving the response to medical and surgical therapy. The metabolic demands of rapid growth and maturation, in addition to low nutritional reserves present during infancy, make the potential benefit of sufficient nutrition for critically ill pediatric patients even greater.

Breast-feeding is the ideal method of feeding an infant and should be continued for at least the first year of life whenever possible. When this is not feasible, various infant formulas are available that provide appropriate nutrients for infants using the oral route. A pediatric patient who has a functioning intestinal tract, but is unable to achieve adequate oral intake, can be fed enterally using a tube inserted into the stomach or small intestine. Indications for providing specialized enteral nutrition include malnutrition, malabsorption, hypermetabolism, failure to thrive, prematurity, and disorders of absorption, digestion, excretion, or utilization of nutrients.

Despite the many formulas and feeding techniques available, several medical and gastrointestinal (GI) dilemmas that limit the use of the GI tract for nutritional support can occur in infants and children. Premature infants with severe respiratory disease, congenital abnormalities of the GI tract, or necrotizing enterocolitis are typical candidates for support with parenteral nutrition (PN). Older children with short bowel syndrome, severe malnutrition, intractable diarrhea, or inflammatory bowel disease have been treated successfully with PN therapy. Pediatric patients receiving chemotherapy for the treatment of malignancies or bone marrow transplant and children with severe cardiac failure also have been successfully rehabilitated with PN.

Many disorders that adversely affect nutrient intake or absorption also have an adverse impact on fluid and electrolyte status. Consequently, fluid, electrolyte, and nutrient management should be approached in an integrated manner. This chapter reviews selected aspects of fluid and electrolyte management and nutrition therapy for the pediatric population.

FLUID AND ELECTROLYTE MAINTENANCE

Management of fluid and electrolyte disturbances involves providing normal daily maintenance requirements and replacing deficits and ongoing losses. To design rational fluid therapy, it is necessary to

know the normal composition of body water, to understand the routes through which water and solutes are lost from the body, and to know the effects of diseases and medications on water and electrolytes. Sodium-containing fluids are often referred to as fractions of normal saline (NS) (0.9% NaCl). NS contains 154 mEq/L of sodium chloride.

Calculation of Maintenance Fluid and Electrolyte Requirements

CASE 103-1

Question 1: P.J., a 2-day-old, 7.72-pound (3.5-kg) term female infant, has developed abdominal distension, and her oral feedings have been stopped. Although P.J. receives nothing by mouth (NPO), her fluid and electrolyte needs must be met intravenously. Her serum electrolytes include the following:

Sodium, 137 mEq/L
Potassium, 4.2 mEq/L
Chloride, 105 mEq/L
CO_2, 23 mEq/L

What are her estimated requirements to calculate a maintenance fluid and electrolyte prescription for her?

General recommendations for calculating maintenance fluid have not changed significantly since first outlined by Holliday and Segar in 1957.[1] However, more current dosing recommendations exist for electrolyte and nutrient replacement and are provided by the American Society for Parenteral and Enteral Nutrition.[2] Fluid, electrolyte, and nutrient requirements on the basis of weight are provided in **Table 103-1**. Although a commercially available intravenous (IV) solution will be used, each component of the solution can be calculated separately. Using the guidelines in Table 103-1, P.J.'s maintenance requirements can be estimated as follows:

Fluid $100\ \text{mL/kg/day} \times 3.5\ \text{kg} = 350\ \text{mL/day}$
or $15\ \text{mL/hour}$

Sodium $2–4\ \text{mEq/kg/day} \times 3.5\ \text{kg} = 7–14\ \text{mEq/day}$ (Eq. 103-2)(Eq. 103-1)

Potassium $2–3\ \text{mEq/kg/day} \times 3.5\ \text{kg} = 7–10.5\ \text{mEq/day}$ (Eq. 103-3)

Table 103-1
Daily Parenteral Nutrient Requirements in Children

Nutrient	Weight/Age	Requirement
Fluid	>1.5 kg	150 mL/kg
	1.5–2.5 kg	120 mL/kg
	2.5–10 kg	100 mL/kg
	10–20 kg	1000 mL + 50 mL/kg for each kg >10 kg
	>20 kg	1500 mL + 20 mL/kg for each kg >20 kg
Calories	Up to 10 kg	100 kcal/kg
	>10–20 kg	1000 kcal + 50 kcal/kg for each kg >10 kg
	>20 kg	1500 kcal + 20 kcal/kg for each kg >20 kg
Protein[a]	Preterm infants (<1 year)	3–4 g/kg
	Term infants (<1 year)	2.5–3 g/kg
	Older children (1–10 years)	1.5–2.5 g/kg
	Adolescents (>10 years)	0.8–2 g/kg
Fat[b,c]	Infants (<1 year)	Initially 0.5–1 g/kg and advance by 0.5–1 g/kg to a goal of 3 g/kg
	Children (1–10 years)	Initially 1 g/kg and advance by 1 g/kg to a goal of 1–2 g/kg
	Adolescents (>10 years)	Initially 1 g/kg and advance by 1 g/kg to a goal of 1–2 g/kg
Dextrose	Infants (<1 year)	Initially 6–8 mg/kg/minute and advance by 1–2 mg/kg/minute to a goal of 10–14 mg/kg/minute (max. 18 mg/kg/minute)

Nutrient	Weight/Age	Requirement
	Children (1–10 years)	Initially 3–6 mg/kg/minute and advance by 1–2 mg/kg/minute to a goal of 8–10 mg/kg/minute
	Adolescents (>10 years)	Initially 2.5–3 mg/kg/minute and advance by 1–2 mg/kg/minute to a goal of 5–6 mg/kg/minute
Electrolytes and Minerals[d]		
Sodium	Infants and children	2–5 mEq/kg
	Adolescents and children (>50 kg)	1–2 mEq/kg
Potassium	Infants and children	2–4 mEq/kg
	Adolescents and children (>50 kg)	1–2 mEq/kg
Chloride and acetate	Infants and children	As needed to maintain acid–base balance
Calcium	Preterm neonates	2–4 mEq/kg
	Infants and children	0.5–4 mEq/kg
	Adolescents and children (>50 kg)	10–20 mEq
Phosphorus	Preterm neonates	1–2 mmol/kg
	Infants and children	0.5–2 mmol/kg
	Adolescents and children (>50 kg)	10–40 mmol
Magnesium	Infants and children	0.3–0.5 mEq/kg

Nutrient	Weight/Age	Requirement
	Adolescents and children (>50 kg)	10–30 mEq
Trace Elements		
Zinc	Preterm neonates	400 μg/kg
	Term neonates (3–10 kg)	250 μg/kg
	Children (10–40 kg)	50 μg/kg (up to 5 mg)
	Adolescents (>40 kg)	2–5 mg
Copper	Infants and children (≤40 kg)	20 μg/kg (up to 500 μg)
	Adolescents (>40 kg)	200–500 μg
Manganese	Infants and children (≤40 kg)	1 μg/kg (up to 55 μg)
	Adolescents (>40 kg)	40–100 μg
Chromium	Preterm neonates	0.05–0.3 μg/kg
	Term neonates and children (≤40 kg)	0.2 μg/kg (up to 5 μg)
	Adolescents (>40 kg)	5–15 μg
Selenium	Infants and children (≤40 kg)	2 μg/kg (up to 100 μg)
	Adolescents (>40 kg)	40–60 μg

[a]"Infant" amino acids contain histidine, taurine, tyrosine, and cysteine, which are essential in infants but not older patients.

[b]Because linoleic acid represents 54% of the fatty acid in soybean oil and 77% in safflower oil, 7% to 10% of calories must be provided as fat emulsion. This can be given daily over the course of 24 hours (preferred in patients predisposed to sepsis and preterm infants) or two to three times weekly.

[c]Fat dosing is based on soybean oil–based emulsion. Refer to product-specific dosing for other formulations.

[d]These doses are guidelines, and all patients should be evaluated individually for appropriateness of dosing. For example, patients with short bowel syndrome may require large doses of magnesium, and patients with renal insufficiency may require none to low amounts of potassium, calcium, phosphorus, and magnesium.

Source: Fluid and Calorie portion taken from Holliday MA, Segar WE. The maintenance need for water in parenteral fluid therapy. *Pediatrics*. 1957;19(5): 823–832; Other portions taken from American Society for Parenteral and Enteral Nutrition. Appropriate Dosing for Parenteral Nutrition: ASPEN Recommendations. 2019:3. Accessed September 11, 2020. https://www.nutritioncare.org/uploadedFiles/Documents/Guidelines_and_Clinical_Resources/PN%20Dosing%201-Sheet-FINAL.pdf. Adapted with permission of the American Society for Parenteral and Enteral Nutrition.

Fluid and electrolyte requirements can be met by infusing a solution of 5% dextrose with one-quarter NS (38 mEq/L) and 20 mEq/L of KCl at 15 mL/hour. This provides 12 mEq (3.4 mEq/kg/day) of NaCl and 7 mEq (2 mEq/kg/day) of KCl in 360 mL (103 mL/kg/day) of fluid per day.

As shown with P.J., to provide general maintenance requirements, hypotonic IV fluids are often used in pediatrics; however, concerns have arisen regarding the risk of hyponatremia. Hospital-acquired hyponatremia can lead to hyponatremic encephalopathy and can cause permanent brain damage. To combat this, the American Academy of Pediatrics (AAP) developed a clinical practice guideline recommending the use of isotonic fluids for maintenance needs in the general pediatric population.[3] Normal serum sodium concentrations range from 135 to 145 mEq/L; thus, NS approximates the sodium concentration of plasma and is often the primary isotonic preparation used. Because of the exclusion criteria used in the studies providing support for the summative recommendations, the guideline does not include neonates younger than 28 days or admitted to the newborn intensive care unit (NICU). Therefore, this

recommendation would not apply to P.J. since she is within the first 28 days of life.

Additionally, daily fluid and electrolyte requirements may be altered when fluid and electrolyte losses are increased or when excretion is impaired. When abnormal losses are present, they must be given back to the patient daily. Replacement fluid is generally provided using NS, giving 1 mL for every 1 mL lost, but can be based on the patient's clinical status.

The requirements for fluid and calories normalized to body weight are much greater in very small children than in older children and adults, as can be seen in Table 103-1. This is because infants have a much larger body surface area relative to weight, lose more fluid through evaporation, and dissipate more heat per kilogram than their older counterparts. Furthermore, very low-birthweight (VLBW) infants cannot concentrate urine and are at an increased risk for dehydration if inadequate fluids are provided.

Dehydration

CASE 103-2

QUESTION 1: H.S. is a 2-year-old lethargic female with a 2-day history of vomiting and minimal oral intake. Yesterday, she required only three diaper changes instead of her usual eight and has needed only one change today. Her vital signs are as follows:

Temperature, 102.2 °F (39 °C)
Pulse, 140 beats/minute (normal, 80–130 beats/minute)
Respiratory rate, 30 breaths/minute (normal, 30–35 breaths/minute)
Blood pressure (BP), 80/45 mm Hg (normal, 80–115 mm Hg systolic and 50–80 mm Hg diastolic)

On physical examination, her eyes appear sunken, her mucous membranes are dry, and her skin is dry and cool to touch. Although she is crying, there are no tears, and the skin over her sternum tents when pinched. Her weight today is 25.13 pounds (11.4 kg); 3 weeks ago, it was 28.44 pounds (12.9 kg).

What do these findings represent? What immediate treatment should be provided?

H.S.'s lethargy, decreased urine output, tearless crying, dry mucous membranes, dry skin with fever, sunken eyes, mild tachycardia with low normal blood pressure, and poor skin turgor are all signs of dehydration. This is consistent with her 2-day history of vomiting and poor intake. Her weight loss of 3.31 pounds (1.5 kg) gives further evidence of the extent of dehydration. Dehydration or fluid loss is determined most accurately by weight loss. A patient's fluid deficit can be estimated using the assumption that 1 g of body weight is ≈1 mL; therefore, J.H.'s deficit can be estimated to be 1500 mL. The percentage of dehydration is estimated using the following formula:

$$\%\ \text{Dehydration} = \text{Normal body weight} - \text{Actual body weight} / \text{Normal body weight} \times 100 \qquad \textbf{(Eq. 103-4)}$$

If recent weights are unavailable, the extent of dehydration can be approximated from physical findings, as described in **Table 103-2**. Tachycardia, decreased urine output, and marginal blood pressure dictate the need for immediate IV rehydration with isotonic fluids, such as NS. In this patient, 20 mL/kg of NS (12.9 kg × 20 mL/kg = 258 mL) should be infused as rapidly as possible to establish normal blood pressure of fluid within the hour. Treatment should be repeated as necessary with monitoring of the patient's heart rate, capillary refill time, and urine output. Stabilization often requires 40 to 60 mL/kg of fluid within an hour.[4] For symptomatic patients, including those with seizures, the serum sodium concentration should be increased acutely only to the degree necessary to abate symptoms.

Table 103-2
Clinical Signs of Dehydration

Severity	Dehydration (%)	Psyche	Thirst	Mucous Membranes	Tears	Anterior Fontanel	Skin	Urine Specific Gravity
Mild	>5	Normal	Slight	Normal to dry	Present	Flat	Normal	Slight change
Moderate	6–10	Irritable	Moderate	Dry	±	±	±	Increased
Severe	10–15	Hyperirritable to lethargic	Intense	Parched	Absent	Sunken	Tenting	Greatly increased

CASE 103-2, QUESTION 2: H.S.'s serum electrolyte results were as follows:

Sodium, 128 mEq/L (normal, 135–145 mEq/L)
Potassium, 3.1 mEq/L (normal, 3.5–5 mEq/L)
Chloride, 88 mEq/L (normal, 102–109 mEq/L)
HCO_3^-, 30 mEq/L (normal, 22–29 mEq/L)

What are her fluid and electrolyte needs? What recommendations for her fluid orders would you provide to the team?

In addition to normal maintenance fluids, H.S. must be provided with fluids and electrolytes to replace her deficit secondary to dehydration and compensate for increased insensible water loss because of fever. Each component of the fluid can be calculated separately, using Eqs. 103-5 to 103-7.

$$\text{Fluid deficit} = \text{Weight loss (kg)} \times 1000\ \text{mL/kg} \quad \textbf{(Eq. 103-5)}$$

$$\text{Fever adjustment} = 10\% \times \text{Maintenance for each } ^\circ\text{C} \geq 37\ ^\circ\text{C} \quad \textbf{(Eq. 103-6)}$$

$$(\text{CD} - \text{CO}) \times F_d \times \text{Weight} = \text{mEq required} \quad \textbf{(Eq. 103-7)}$$

where CD is the concentration of sodium desired (mEq/L), CO is the concentration observed (mEq/L), F_d is the apparent distribution factor as a fraction of body weight (**Table 103-3**), and weight is the baseline weight before illness (kg). In consideration of both maintenance needs and current deficits, fluid and electrolyte requirements for H.S. would be estimated as follows.

Table 103-3
Electrolytes and Apparent Distribution

Electrolyte	F_d (L/kg)
Sodium	0.6–0.7
Bicarbonate	0.4–0.5
Chloride	0.2–0.3

F_d, apparent distribution factor as a fraction of body weight.

FLUID

$$\begin{aligned}
&\text{Maintenance} && 1000\ \text{mL} + (50 \times 2.9) = 1145\ \text{mL} \\
&\text{Fever} && 2\ ^\circ\text{C} \times 0.1\ (1145) = \ \ 229\ \text{mL} \\
&\text{Deficit} && 1.5\ \text{kg} \times 1000\ \text{mL/kg} = \underline{1500\ \text{mL}} \\
& && \text{Total fluid} = 2874\ \text{mL}
\end{aligned}$$

(Eq. 103-8)

SODIUM

$$\text{Maintenance } 3\ \text{mEq/kg} \times 12.9\ \text{kg} = 38.7$$

$$\text{Deficit } (135 - 128\ \text{mEq/L}) \times 0.6\ \text{L/kg} \times 12.9\ \text{kg} = 54.2$$

$$\text{Total sodium} \sim 93\ \text{mEq}$$

(Eq. 103-9)

CHLORIDE

H.S. has a mild metabolic alkalosis as evidenced by her serum chloride of 88 mEq/L and her serum bicarbonate of 30 mEq/L. This is most likely because of the loss of hydrogen and chloride in her vomitus. Thus, both the sodium and potassium replacements should be administered as chloride salts.

POTASSIUM

Potassium is primarily an intracellular ion. It moves in and out of cells in exchange for hydrogen ions to maintain a normal blood pH. Therefore, in metabolic alkalosis, the intracellular shift of potassium will decrease the serum potassium concentration. When the pH normalizes, as will occur with rehydration, the hydrogen ions will move intracellularly and the potassium will move extracellularly, thus causing the serum potassium concentration to increase. Additionally, potassium is also excreted by the kidney in exchange for hydrogen ion conservation. These factors make the serum potassium concentration difficult to interpret. Intravascular volume depletion

causes hypoperfusion of the kidney and can result in acute renal failure; therefore, the prudent approach is to give no potassium until urine output is clearly established. Then, only maintenance doses of potassium should be administered until a normal acid–base and fluid status are established, and the serum potassium can be assessed more accurately. Hence, H.S. should receive ~26 to 39 mEq of potassium (2–3 mEq/kg × 12.9 kg) once urine flow is established.

Administration of Fluid Requirements

Case 103-2, Question 3: J.H.'s nurse asks for details of how the fluid therapy should be administered. How should these calculated needs be given?

Requirements for the first 24 hours of parenteral fluid therapy should provide ~2875 mL of fluid to account for maintenance fluid needs, fever replacement, and deficit replacement. In addition to fluid, at least 93 mEq of sodium (maintenance needs plus deficit replacement) should be provided in the first 24 hours. Rehydration fluids are usually dispensed in volumes less than the 24-hour requirement. This is to prevent wasting IV fluids caused by changes in electrolyte needs during replacement therapy. Because this patient requires ~3 L of fluid, only 1 L would be prepared initially, and this would likely consist of dextrose 5% and 0.45% NS (or greater). Approximately 15 mEq/L of potassium would be added to the next liter of IV solution if the patient had a reasonable urine output.

Historically, the infusion rate was calculated to provide one-third of the daily maintenance fluid plus one-half of the deficit replacement during the first 8 hours. The remainder of the maintenance fluid (adjusted for fever) and deficit replacement was administered during the next 16 hours. However, if appropriate fluid resuscitation is administered as fluid boluses, the need for this complicated calculation is no longer recommended by the AAP. Replacing the deficit calculation plus maintenance fluids over 24 hours is acceptable and without the risk of a fluid error.[5] Usually, serum electrolytes are monitored every 6 to 8 hours during rehydration to

ensure that appropriate electrolytes are being provided. Also, the change in concentration of serum electrolytes is monitored frequently. In general, the serum sodium concentration should not be increased by more than 12 to 15 mEq/L/day.[5] After the initial fluid deficits are replaced, the IV fluid infusion rate would be decreased to 48 mL/hour (1152 mL or approximately maintenance fluid rate).

Dehydration Associated With Diarrhea

CASE 103-3

Question 1: S.B. is a 4-month-old, 13.00-pound (5.9-kg) male presenting with a 4-day history of diarrhea (five to eight large, liquid stools each day). On a well-child visit 4 weeks ago, his weight was 13.23 pounds (6 kg). Since the onset of diarrhea, he has only been receiving oral rehydration fluids. Physical examination reveals the following:

Temperature, 101.84 °F (38.8 °C)
Pulse, 110 beats/minute (normal, 80–160 beats/minute)
Respirations, 45 breaths/minute (normal, 20–40 breaths/minute)
BP, 100/58 mm Hg (normal, 75–105 mm Hg systolic and 40–65 mm Hg diastolic)

His skin is pale, warm, and dry. He is very irritable, and his mucous membranes are dry. The parents report the same number of wet diapers. S.B.'s laboratory values are as follows:

Sodium, 159 mEq/L
Potassium, 3.3 mEq/L
Chloride, 114 mEq/L
CO_2, 12 mEq/L
Blood urea nitrogen (BUN), 22 mg/dL
Creatinine, 0.9 mg/dL

How do S.B.'s history and physical findings correlate with the reported laboratory values?

Diarrheal fluid losses commonly contain high concentrations of bicarbonate, accounting for S.B.'s metabolic acidosis. This, in turn, has resulted in a rapid respiratory rate as the body attempts to compensate for the acidosis by eliminating carbon dioxide. The

increased insensible water losses of fever and tachypnea have resulted in the loss of water in excess of sodium, producing hypernatremia.

CASE 103-3, QUESTION 2: How should S.B.'s dehydration be managed?

S.B. has relatively normal vital signs (specifically a normal heart rate and urine output); therefore, a fluid bolus will not be necessary. Hypernatremia in S.B. indicates fluid losses in excess of sodium, and this should be corrected. With hypernatremia, the central nervous system (CNS) increases intracellular osmolarity load to prevent intracellular dehydration of cells in the CNS. Rapid correction of hypernatremia can cause excessive movement of water into the cells of the CNS and has been associated with seizures. Therefore, S.B.'s fluid and electrolyte deficits should be corrected over the course of 2 to 3 days at a consistent rate, rather than rapidly. In general, serum sodium should not be decreased more than 0.5 mEq/hour (maximum, 12–15 mEq/L/day).[5]

S.B.'s requirements are estimated using the same methods described previously. First, the approximate extent of dehydration must be estimated. S.B.'s weight of 13.23 pounds (6 kg) at the time of his well-child visit at 3 months of age was at the 50th percentile. If his growth has continued at this rate, his current pre-illness weight should be ~14.33 pounds (6.5 kg).[6] This weight should be used to calculate his maintenance requirements. Thus, his water deficit is ~0.6 L, or 9%. Using this approximation, his fluid and electrolyte requirements can be estimated as follows.

FLUID

Maintenance	$6.5 \times 100\ \text{mL/kg} = 650\ \text{mL/24 hours}$
Fever	$1.8\ ^{\circ}\text{C} \times 0.1\ (650\ \text{mL}) = 117\ \text{mL/24 hours}$
	$600\ \text{mL/3 days} = 200\ \text{mL/24 hours}$
Deficit	Total daily needs = 967 mL or 40 mL/hour

SODIUM

(Eq. 103-10)

Maintenance	3 mEq/kg × 6.5 kg = 19.5 mEq/24 hours
Deficit	This is calculated as total body deficit (normal–actual)
Normal	145 mEq/L × 0.6 L/kg × 6.5 kg = 566 mEq
Actual	159 mEq/L × 0.6 L/kg × 5.9 kg = 563 mEq
Deficit	= 3 mEq or 1 mEq/day

(Eq. 103-11)

POTASSIUM

As discussed in Case 103-2, Question 2, the serum potassium value of 3.3 mEq/L may not be indicative of S.B.'s total body potassium status. A metabolic acidosis in S.B. should have facilitated the movement of hydrogen ions into the cells and the movement of potassium from the intracellular to the extracellular space. Thus, the serum potassium of 3.3 mEq/L probably indicates a total body deficit. Therefore, a maintenance potassium dosage of 13 to 20 mEq/day (~2–3 mEq/kg) of potassium should be added to the IV fluid. Serum electrolytes should be measured every 8 to 12 hours, and the intake of all electrolytes should be readjusted based on the results.

BICARBONATE

Although the patient has a metabolic acidosis, the AAP recommends sodium bicarbonate not be administered unless the patient is cardiovascularly unstable, which they are not. Correction of the patient's dehydration should allow for a slow correction of the acidosis.

Case 103-3, Question 3: What replacement fluid for S.B.'s therapy would you recommend?

S.B.'s fluid and electrolyte maintenance requirements and deficits should be corrected with dextrose 5% and ~0.2% NS. An infusion of this solution at 43 mL/hour should correct approximately one-half the

calculated fluid deficits within 24 hours in addition to his normal daily doses. After he urinates, 15 mEq/L KCl can be added to the next liter of solution to provide ~2.6 mEq/kg/day to this patient. The concentration of serum electrolytes should be measured often, and the concentration of electrolytes in the replacement fluid should be adjusted every 8 to 12 hours based on laboratory results. The amount of fluid replacement should be modified based on whether this patient's diarrhea has resolved and the fever has subsided.

Rehydration of the dehydrated patient may be achieved by either the oral or IV route. In some patients, vomiting may preclude effective oral rehydration. If the losses are diarrheal and with no vomiting, the oral route may be a cost-effective alternative to the parenteral route. Various solutions have been used to rehydrate children orally. In an asymptomatic dehydrated child, the sodium concentration of an oral rehydration fluid should contain at least 70 mEq/L of sodium.[5]

The composition of several products is shown in **Table 103-4**. A glucose concentration of 2% optimizes water and electrolyte absorption from the GI tract[5]; more concentrated glucose solutions can worsen rather than ameliorate diarrhea. Use of the oral route and the more concentrated sodium solutions may allow safe rehydration of hypernatremic dehydration in a shorter time frame than the 2 to 3 days previously noted.[5]

Table 103-4
Composition of Oral Rehydration Products

Product	Na^+ (mEq/L)	K^+ (mEq/L)	Cl^- (mEq/L)	Bicarbonate Source (mEq/L)	Carbohydrate (%)
Enfalyte®	50	25	45	34 citrate	3
Rehydralyte®	75	20	65	30 citrate	2.5
Pedialyte®	45	20	35	30 citrate	2.5
WHO salts	75	20	65	30 bicarbonate	2

WHO, World Health Organization.

INFANT ENTERAL NUTRITION

Caloric requirements of infants can be estimated using the formula provided in Table 103-1. The American Heart Association has suggested that infant feeding can be divided into three stages.[7] In the nursing period, only liquids are provided. During the transitional period, solid foods are introduced, but human milk, or commercially prepared infant formula, still provides the major source of the infant's caloric and nutrient supply. In the modified adult period, most nutrition is derived from the solid foods consumed by other household members.

At birth, the human GI tract is adapted for the consumption of a human milk–based diet. Intestinal lactase is present from 36 weeks' gestation and exhibits its maximal activity during infancy. Pancreatic amylase secretion is low, and the bile salt pool is decreased relative to that of older persons, resulting in decreased fat absorption.[8] Human milk provides nutrients in their most usable form for the developing GI tract.

Human Milk Feeding

CASE 103-4

QUESTION 1: M.E. is a 1-day-old full-term infant. M.E.'s mother will breast-feed M.E.

What are the nutritional implications of this decision for M.E.?

Human milk is the ideal food for a human infant and should be encouraged to continue throughout the first year of life as long as desired by both mother and child.[9] There are three phases to human milk production. During the first 5 days of lactation, a viscous, yellow liquid known as *colostrum* is produced. Colostrum is rich in protein, minerals, and other substances (eg, immunoglobulins). During the next 5 days, transitional milk is produced, and in the last phase,

mature milk is produced. The exact nutritional content of human milk varies from mother to mother; however, mature milk provides sufficient protein, minerals, and calories regardless of the mother's nutritional status. Mature human milk generally provides 70 kcal/100 mL, and fat accounts for more than 50% of the caloric content.[10] The fat in human milk is highly digestible and absorbable.[10] An additional 40% of calories is provided as carbohydrates, primarily in the form of lactose, and the remaining 10% is provided as protein. Whey and casein are the two primary proteins in mature human milk, with whey being the major protein component (whey-to-casein ratio of 60:40).[11] Human milk is of such biologic quality and bioavailability that adequate growth can be attained with a lower overall intake of protein than is provided by commercially prepared infant formulas, which contain lower whey-to-casein ratios.[11]

The iron content of human milk is low; however, supplementation may be unnecessary in healthy breast-fed infants early in life.[12] Not only is the iron in breast milk highly absorbed, but infants also have iron stores within the body. Regardless of maternal status, the vitamin D content of human milk is inadequate. Thus, M.E. will require 400 international units of vitamin D while she is exclusively breast-fed.[13]

Additionally, human milk provides the infant with protection against a wide variety of infectious diseases, including otitis media, diarrhea, pneumonia, and bronchiolitis. Evidence further suggests that human milk provides protection against noninfectious disorders, such as allergies, inflammatory bowel disease, insulin-dependent diabetes mellitus, and sudden infant death syndrome.[9,10] Human milk contains immunologically active cellular components and antibodies. These include secretory immunoglobulin A (IgA), both T and B lymphocytes, macrophages, and neutrophils.[9,10] The lipases and amylase present in human milk may facilitate the digestion of fat and carbohydrates in the still-developing GI tract. Proteins present in human milk serve as carriers for trace minerals and facilitate their absorption.[11] Oligosaccharides and glycopeptides may promote the colonization of the GI tract by *Lactobacilli* and decrease colonization

by *Bacteroides*, *Clostridia*, enterococci, and gram-negative rods, all of which may be pathogenic.[10]

Case 103-4, Question 2: What potential complications are associated with breast-feeding? What instructions should be given to M.E.'s mother?

Complications associated with breast-feeding are few; however, there are some potential problems. "Breast milk jaundice" associated with an indirect (unconjugated) hyperbilirubinemia can occur in the breast-fed infant during the first week of life and generally resolves by the fourth week of life. Although the infant's skin, sclera, and palate become yellow, this is generally not a dangerous condition. Nevertheless, if the bilirubin level becomes too high, the infant could develop an encephalopathy known as kernicterus. However, it is generally not necessary for the mother to stop breast-feeding while the infant has jaundice. The AAP recommends that infants nurse at least 8 to 12 times daily while jaundiced.[14] Some maternal infections have the potential to be transmitted to the infant during breast-feeding. Human immunodeficiency virus (HIV) and human T-lymphotropic virus 1 (HTLV-1) can be transmitted via breast milk, and therefore, maternal infections with these viruses are contraindications to breast feeding.[9,10] Other viruses, such as herpes simplex virus, can be transmitted if contact with active lesions occurs during breast-feeding. Similarly, some medications taken by the mother are detectable in her breast milk; however, only a few agents (eg, antineoplastics, radiopharmaceuticals, ergot alkaloids, iodides, atropine, lithium, cyclosporine, chloramphenicol, bromocriptine) are absolute contraindications to breast-feeding.[9,10]

Case 103-4, Question 3: M.E.'s mother suffers from migraine headaches, which have increased in frequency since M.E.'s birth. M.E.'s mother takes an ergot alkaloid for the acute management of her headaches and therefore has decided not to breast-feed M.E. She will be using infant formula instead. How are these products prepared, and how do they differ from human milk?

Because of the excretion of ergot alkaloids into breast milk and the risk for toxicity to the infant, it is advisable to either select an alternative medication or discontinue breast-feeding and use an infant formula. According to the AAP guidelines for commercially prepared infant formula composition, formula should provide 20 kcal/ounce, osmolality should be between 300 and 400 mOsm/L, protein quantity should be a minimum of 1.8 g/100 kcal and should not exceed 4.5 g/100 kcal, and fat quantity should be between 3.3 and 6 g/100 kcal, supplying between 30% and 54% of calories. Infant formulas generally begin with a cow's milk base; however, intolerance to pure cow's milk has resulted in several modifications. The predominant protein in cow's milk is casein, which is more difficult for infants to digest than the human milk protein, whey. Consequently, infant formulas generally have less casein than cow's milk, although not to the level of human milk. The casein present in cow's milk formulas also may be heat-denatured to improve its digestibility. In addition, the fat source in cow's milk is replaced by one of several vegetable oils, allowing for easier digestion. Last, the carbohydrate source in cow's milk–based formula is supplemented with lactose or sucrose because the lactose content of cow's milk is only 50% to 70% of that in human milk. Soy-based and protein hydrolysate formulas are available for infants who are intolerant of cow's milk–based formulas.

Soy-based formulas use soybean as the protein source.[15] The soy is heat-treated to enhance protein digestibility and improve the bioavailability of some nutrients. Although nutrients, such as methionine, zinc, and carnitine, are still present, their concentrations are relatively low. Therefore, the manufacturer routinely adds methionine to all soy-based formulas. Zinc and carnitine may not be added, and exogenous supplementation may be necessary. Soy-based formulas substitute sucrose, corn syrup, or a combination of the two for lactose as the carbohydrate source. Additionally, soy protein formulas are more expensive than cow's milk–based formulas. The AAP recommends that the use of soy-based formula be limited to patients with primary lactase deficiency (galactosemia), patients with secondary lactose intolerance from enteric infections or

other causes, vegetarian families in which animal protein formulas are not desired, and infants who are potentially cow's milk protein allergic, but who have not demonstrated clinical manifestations of allergy. Long-term use of soy-based formulas in premature and low-birthweight infants should not be recommended. Soy-based formulas have aluminum contamination and have been associated with the development of rickets. Soy-based formulas are also not recommended for infants with documented allergic reactions to cow's milk protein because of the potential for cross-antigenicity between the two proteins. Additionally, soy protein formulas are not recommended for the routine management of colic.

Elemental formulas, made with hydrolysate formulas, are another option for infants who have an intolerance to cow's milk–based formulas. The milk proteins (ie, casein and whey) are heat-treated and enzymatically hydrolyzed to enhance the digestibility of protein hydrolysate formulas, which are fortified with additional amino acids that are lost during processing. As with soy protein formulas, protein hydrolysates substitute sucrose, tapioca, or corn syrup for lactose as the carbohydrate source. Protein hydrolysate formulas often include significant amounts of medium-chain triglycerides because they are easily absorbed. Because the proteins are extensively hydrolyzed, these formulas are considered the least allergenic of the infant formulas and therefore may be appropriate for infants with a true allergy to cow's milk protein. Nevertheless, prospective studies on the safety of such a substitution in human infants have not been undertaken because of the ethical concerns associated with intentionally exposing infants with documented allergies to a potential allergen. Protein hydrolysate formulas are the least palatable of the available pediatric formulas and are more costly.[16]

Infant formula is available from the manufacturers in three forms: ready-to-feed formula, powder for reconstitution, and concentrated liquid. The ready-to-feed form is the most convenient but also the most expensive. The powder and concentrated liquid are less expensive; however, both require that predetermined amounts of boiled water be added before use. To save money, some parents dilute infant formula to a greater extent than recommended to make

their supply last longer. This practice should be discouraged because of the risk of hyponatremia and, ultimately seizures, with excessive free water intake in infants younger than 1 year of age. In addition, the infant will not receive the appropriate amount of calories for normal growth and development. Similarly, supplementing an infant's diet with free water, for any reason, may also result in hyponatremia and seizures and should be discouraged. Periodically, manufacturing problems can occur, resulting in the recall of a product from the market.[17] Therefore, it is important for the patient's health care providers to stay informed of manufacturers' recalls.

Introduction of Cow's Milk

Case 103-4, Question 4: At age 2 months, M.E. is found to have a hematocrit (Hct) of 33% (normal, 35%–45%). After questioning her mother, you learn that M.E. was taken off infant formula 1 month ago and changed to whole cow's milk to decrease food costs. How are these two findings related, and how should M.E. be managed?

The use of cow's milk is not recommended for infants younger than age 1 year. The iron in cow's milk is present in inadequate concentrations and is absorbed poorly from the human GI tract. For this reason, most infant formulas are fortified with iron. Raw cow's milk is also insufficient in vitamin E and essential fatty acids.[18] It also does not contain taurine, an amino acid important in retinal development. Furthermore, cow's milk contains excessive amounts of solute that cannot be eliminated by the immature kidney.

To treat M.E.'s anemia, iron should be added to her diet. This can be done by changing back to an iron-fortified infant formula, feeding her an iron-fortified cereal, or giving a therapeutic ferrous sulfate liquid medication. The appropriate iron replacement dose for severe anemia is 4 to 6 mg/kg/day of elemental iron in divided doses with follow-up of the infant's hemoglobin and hematocrit.

Introduction of Solid Foods

Case 103-4, Question 5: At age 4 months, M.E.'s mother asks about the introduction of "baby foods" into M.E.'s diet. How should the clinician respond?

Human milk or commercially prepared infant formula provides adequate nutrition for an infant for the first 12 months of life. Introduction of solid foods before 4 months of life, although common in the past, is discouraged because younger infants are unprepared to swallow foods other than liquids. Solids (first cereals, then fruits, and vegetables) should be introduced when the child has good control of the head and neck movements (ie, usually at 4–6 months old).[7] Preferably, one new food should be introduced at a time, at 1-week intervals, to allow for assessment of food allergies.

Therapeutic Formulas

CASE 103-5

Question 1: L.B. is a 2-week-old infant whose newborn screen is positive for phenylketonuria (PKU). Discuss the concepts behind the production of therapeutic formulas and the dietary management of patients with inborn errors of metabolism.

How should L.B.'s diet be modified?

Inborn errors of metabolism are disorders in which an enzyme or its cofactor is absent or insufficient to meet metabolic demands.[19] As a result, one or more precursor compounds in a metabolic pathway can accumulate before the defective step. Correspondingly, one or more metabolic products that normally would have been generated after the defective step in the metabolic pathway are not sufficiently available.

The dietary management of metabolic errors is based on the following strategies:

- Reduce the intake of a precursor compound that cannot be metabolized.

- Supplement the deficient compounds that would have been produced if the normal metabolic pathway had not been blocked.
- Add a substrate that provides an alternative pathway for the elimination of an accumulated toxin.

Therapeutic formulas are designed to reduce the intake of precursor compounds or to provide the deficient metabolic end product.

When hydroxylation of phenylalanine to tyrosine does not take place, phenylalanine accumulates in the blood and results in mental retardation. Because PKU has been diagnosed in L.B., his diet should be modified using a formula containing little or no phenylalanine. The tyrosine deficiency of PKU can also be managed by the addition of tyrosine to the phenylalanine-free therapeutic formulas that are available for patients with PKU. When L.B. progresses to solid foods, it will be important to limit or avoid foods that contain high levels of protein such as eggs and soybeans.

Other metabolic errors present in infancy include galactosemia (galactose cannot be metabolized to glucose), homocystinuria (methionine is not converted to cysteine), urea cycle disorders (ammonia detoxification is impaired), and maple syrup urine disease (metabolism of the branched-chain amino acids leucine, isoleucine, and valine is blocked).

These metabolic errors are managed by manipulating the diet.[19] In galactosemia, the carbohydrate source should not contain galactose or lactose. In homocystinuria, methionine should be present only in quantities sufficient to meet basic requirements, and cysteine should be supplemented. In the urea cycle disorders, protein often is provided only as essential amino acids, and a high-energy diet is provided to maximize the formation of nonessential amino acids from nitrogen and to minimize ammonia production. In maple syrup urine disease, natural protein is fed in small quantities to provide the minimal requirement of branched-chain amino acids, and a branched-chain amino acid-free supplement is added to provide adequate protein intake.

Route of Administration

Nutritional support using the GI tract is the preferred approach when possible. Enteral nutrition provides several advantages. First, interposition of the GI mucosa between the nutrient supply and circulation allows absorptive function to provide a homeostatic control. Second, the flow of nutrients from the GI tract to the liver via the portal circulation before reaching systemic circulation also assists homeostatic control. Third, the lack of enteral nutrition allows normal GI tract flora to overgrow and translocate into the blood, resulting in bacteremia. Finally, the intestinal mucosa depends on intraluminal absorption for much of its energy supply. Hence, provision of at least a small amount of enteral feeding, referred to as trophic feeds, helps to ensure a healthy GI tract and may facilitate advancement to full enteral feedings at the appropriate time.[20]

Normal oral feeding is the most basic method for patients who are willing and able to eat or drink. Patients whose GI motility, structure, and function are normal, but whose oral feeding is prevented by an altered state of consciousness, uncoordinated sucking and swallowing, or other conditions that prevent adequate oral ingestion can be fed by a GI tube in intermittent boluses or by continuous infusion.

Bolus tube feedings more closely mimic the normal state. They periodically distend the stomach, which aids in gastric secretion and emptying. When bolus tube feeding is undertaken, the volume of formula or expressed breast milk required to provide sufficient calories for a 24-hour period is administered through the tube in equal aliquots every 2, 3, 4, or 6 hours. The frequency of administration depends on the patient's age, gastric capacity, and the infant's ability to maintain a normal serum glucose concentration between feedings. In general, younger and more premature infants require more frequent feedings. Intolerance to bolus tube feedings can be manifested as diarrhea, gastroesophageal reflux with emesis, or poor motility. Poor motility is usually apparent when large volumes of feeding, referred to as residuals, remain in the stomach when the next feeding is due.

Continuous tube feedings can be given at a constant rate of infusion by pump into the stomach or duodenum when bolus feedings have failed. This approach may be better tolerated by premature infants and children with diarrhea.

Patients with intrinsic GI disease (**Table 103-5**) or malabsorption may require total or supplemental PN. Concurrent administration of low-volume, trophic enteral feedings may provide important nutrients to the gut mucosa even when the parenteral route supplies all of the necessary systemic nutrients.[20] Administration of PN into a peripheral vein is usually restricted to patients expected to require parenteral feeding for a short time (ie, 2 weeks or less) because the amount of nutrients that can safely be infused peripherally is limited. In patients who require long-term PN, the IV solution is more concentrated and must be administered into a central vein.

Table 103-5

Common Indications for Parenteral Nutrition Support[a]

Extreme prematurity
Respiratory distress
Congenital GI anomalies
Duodenal atresia
Jejunal atresia
Esophageal atresia
Tracheoesophageal fistula
Pyloric stenosis
Congenital webs
Hirschsprung disease
Malrotation
Volvulus
Abdominal wall defects
Omphalocele (herniation of viscera into the umbilical cord base)
Gastroschisis (defect of abdominal wall, any location except umbilical cord)
Congenital diaphragmatic hernia

Necrotizing enterocolitis
Chronic diarrhea
Inflammatory bowel disease
Chylothorax
Pseudo-obstruction
Megacystis microcolon
Abdominal trauma involving viscera
Adverse effects of treating neoplastic disease
Radiation enteritis
Nausea and vomiting
Stomatitis, glossitis, and esophagitis
Anorexia nervosa
Cystic fibrosis
Chronic renal failure
Hepatic failure
Metabolic errors

GI, gastrointestinal.

[a]Other indications for parenteral nutrition may exist.

Nutritional Assessment

CASE 103-6

Question 1: T.C. is a 4-month-old, lethargic male. On examination, he has a moderately distended abdomen and dry mucous membranes. No other remarkable abnormalities are noted. His weight is 14.33 pounds (6.5 kg) (50th–75th percentile for age). Previously, when he was 2 months old, T.C. weighed 12.35 pounds (5.6 kg) (75th percentile for age), and his length was 57 cm (50th percentile for age). His mother reports that for the past 5 to 7 days, he has had five to eight large, liquid stools per day. His infant formula has not changed. He is to be hospitalized for evaluation of his diarrhea and weight loss and for fluid and nutritional management.

After correction of his initial fluid and electrolyte deficits, an assessment of his nutritional status shows the following:

Weight, 14.33 pounds (6.5 kg; 50th–75th percentile)
Length, 24.51 inches (62 cm; 50th percentile)
Albumin, 3.8 g/dL (normal, 4–5.3 g/dL)
Prealbumin, 7 mg/dL (normal, 20–50 mg/dL)

How would you assess T.C.'s nutritional status?

Growth assessment is an important focus of pediatric health care, especially during the first year of life. With the exception of the intrauterine period, the most rapid growth occurs during the first year. On average, a normally growing infant gains ~30 g/day. Typically, healthy infants weigh approximately three times their birthweight by their first birthday.

The patient's nutritional status should be assessed before beginning a nutritional support regimen and reassessed at regular intervals during the course of treatment. If the patient was previously well nourished, the goal is to maintain that status until a normal diet can be resumed. In a child who was previously malnourished, an effort should be made to promote "catch-up" growth and normalize the biochemical nutritional measures. One in five children admitted to the hospital experience acute or chronic malnutrition.[21] Malnutrition in children is a risk factor for decreased social skills and impaired intellectual development.[22]

Anthropometric measurements, including height, weight, and head circumference, are used to determine nutritional status in infants and children and can help in assessing T.C.'s condition. Standards for these measurements have been derived from pediatric patients in the United States and compiled into graphs referred to as growth curves (http://www.cdc.gov/growthcharts).[6] An individual patient's measurements are compared with the graph of normal values for that specific age group. As prematurely born infants age, a standard growth curve adjusted for prematurity can be used. Using these measurements, comparisons with standards are possible: weight for age, height for age, and weight for height.[6] A weight that is below the fifth percentile for the patient's height is considered an indication of acute malnutrition. Similarly, a height and weight that are below the fifth percentile for the patient's age indicate chronic malnutrition. It is

important to consider the height and weight of the child's parents because genetics are important determinants of the height and weight that a child may ultimately achieve. Additionally, the revised growth charts include the body mass index (BMI) for age for children older than 2 years. The BMI helps identify children at risk for obesity and type 2 diabetes, two problems that have recently become concerns within pediatrics.[6]

Numerous biochemical indices are also used in the assessment of nutritional status. Of these, the most readily available and widely used is the serum albumin concentration. Although a low serum albumin can be a specific indicator of protein-calorie malnutrition, its long half-life (20 days)[21] makes it an insensitive indicator for developing and resolving malnutrition.

Prealbumin can also function as a biochemical marker of nutritional status.[21] Because of its shorter half-life, prealbumin has the advantage of being more sensitive than albumin to acute nutritional changes, and it is still useful when exogenous albumin infusions are given.[21] Other measurements used in adults, such as 24-hour creatinine excretion, 24-hour nitrogen excretion, and nitrogen balance, are reserved for older children because complete collections of urine are difficult to obtain and the percentage of non-urea nitrogen present in urine is variable in infants.

CASE 103-6, QUESTION 2: After initial IV rehydration and receiving nothing by mouth (NPO) for 48 hours, T.C.'s stool output has decreased dramatically. Is this characteristic of infants with chronic diarrhea? How should T.C.'s enteral diet be initiated?

A prompt decrease in stool output when enteral intake is stopped is typical of infants with chronic diarrhea. Nonetheless, evaluation of bowel function and adaptation has shown that enteral nutrition is superior to PN with regard to histologic recovery, improvement of D-xylose absorption, protein absorption, and disaccharidase activity.[23] In fact, improvement in histology or absorptive function might not occur until enteral nutrients are given.[20] Thus, for T.C., every effort should be made to provide some nutrition enterally.

The enteral regimen should be initiated with a lactose-free formula, such as an elemental formula or a soy-based formula. Although any soy-based formula would be appropriate, Isomil DF is a soy-based formula with added fiber that is indicated for infants with diarrhea. Infants with chronic diarrhea can have small bowel mucosal damage and decreased disaccharidase activity.[7] Carbohydrate absorption depends on the digestion of disaccharides and polysaccharides to monosaccharides through disaccharidase activity in the intestinal lumen. Substitution of free glucose orally may overcome the problem of carbohydrate digestion and absorption. Administration of large amounts of oral glucose should be limited, however, because of its osmotic effect and potential to worsen diarrhea. Furthermore, incompletely absorbed carbohydrate is available to colonic bacteria for fermentation, the end products of which can produce diarrhea through colonic irritation.

Unlike carbohydrate, protein rarely causes diarrhea, but the mucosal damage present in patients with chronic diarrhea, such as T.C., can reduce the absorptive surface area so that protein malabsorption may occur. This can be minimized through the administration of a formula containing protein in the form of dipeptides and tripeptides, which are absorbed more efficiently than free amino acids.

Dilution of hypertonic formulas to half strength may improve formula tolerance. The concentration is increased in a stepwise fashion to full strength if there is no carbohydrate malabsorption and if stool output is not excessive. Tolerance may be improved by continuous infusion of the enteral product. If enteral refeeding results in the return of diarrhea, fluid and electrolytes must be replaced with an equal volume of an IV solution of similar electrolyte composition to the stool loss.

Case 103-6, Question 3: How can T.C.'s tolerance to the formula and his recovery of intestinal function be assessed?

Malabsorption or formula intolerance can be assessed by stool studies, which would include assessing for the presence of reducing substances and stool pH. Lactose is a reducing sugar, and its presence in stool is an assessment of carbohydrate absorption. The bacterial fermentation products of malabsorbed carbohydrates can result in a decreased stool pH, which suggests malabsorption. To further evaluate carbohydrate absorption, D-xylose may be given orally; a blood sample is drawn 4 to 5 hours later to determine the amount absorbed. This test may be of initial prognostic value in predicting which patients will require prolonged courses of treatment.[23] More than 5% of ingested fat in a stool collection (typically obtained for 3 days) is indicative of fat malabsorption. All these tests can be evaluated during outpatient visits to guide the refeeding process.

Once the diarrhea has resolved, standard infant formula feedings should be established using an enteral elemental or soy-based formula. Regardless of the time chosen, a gradual stepwise conversion is suggested. A small volume of standard formula is substituted for an equal volume of elemental or soy-based formula, and the substitution volume is increased daily until the elemental or soy-based formula is eliminated completely from the regimen. If a specific nutrient intolerance has been identified, a standard formula that does not contain that nutrient must be selected. For example, a patient with cow's milk protein intolerance may require a soy protein formula or an elemental formula.

Pediatric Parenteral Nutrition

The basic requirements for a parenteral nutrient regimen are listed in Table 103-1. These guidelines for the initiation of a nutrient regimen should be individualized to specific patient needs. The correct regimen for any specific patient is one that supplies sufficient nutrients to promote a normal rate of growth without toxicity. In particular, patients with ongoing, abnormal nutrient losses may require much larger doses of certain nutrients. Individualization of

the nutrient prescription cannot be overemphasized. Many of the requirements listed in Table 103-1 apply to nutrients administered by the enteral route as well. In some instances, the absorption of a particular nutrient from the GI mucosa is incomplete, and enteral requirements are substantially higher. This is particularly true of the major minerals (calcium, magnesium, and iron) and trace elements.

Indications

PN is indicated for any infant or child unable to take in sufficient nourishment to maintain normal growth. Some specific indications are listed in Table 103-5.

VERY LOW-BIRTHWEIGHT INFANTS

Extremely premature or VLBW infants require specialized nutritional support for two distinct reasons. First, the third trimester in utero is a time of rapid growth and accumulation of protein, glycogen, fat, and minerals.[24] The infant born in the very early stages of the third trimester does not accumulate these stores and, therefore, must receive nutrients earlier than a more mature infant. Second, extreme prematurity is associated with poor coordination of the suck and swallow reflex, poor GI motility, and incomplete absorption. Therefore, enteral nutrients may need to be administered via an orogastric or nasogastric tube, and PN supplementation may be required. PN, especially containing amino acids, should be initiated soon after birth to duplicate intrauterine growth and prevent a catabolic state in the first few days of life. The fetus has a continuous supply of amino acids that is immediately stopped after preterm birth.[25] A standardized solution containing amino acids and dextrose can be used for infants weighing <2.20 pounds (<1 kg) in the first 24 hours of life. There has been some reluctance to administer amino acids this soon after birth because of the increased risk of hyperammonemia, uremia, and metabolic acidosis. Several studies, however, have shown early introduction of amino acids is safe,

provides a positive nitrogen balance, and promotes better health outcomes.[26,27]

RESPIRATORY DISTRESS

Respiratory distress may preclude the ability to consume sufficient nutrients enterally because high respiratory rates prevent coordinated breathing and swallowing. In infants who are hypoxic, or at high risk for hypoxia, aggressive enteral feedings during the acute phase of their illness can increase the likelihood of bowel ischemia. Often, these situations are resolved in 3 to 5 days, but this can rarely be predicted at the outset. Trophic feedings (1–5 mL/hour) are often implemented to maintain GI tract integrity. Nutritional support in such cases is initiated by giving parenteral fluids, which provide dextrose as a caloric source. This allows the infant to conserve endogenous energy substrates, an important consideration for the VLBW infant whose entire body composition may contain as little as a 3- to 4-day energy supply.[24] PN should be initiated as soon as it becomes clear the enteral feeding will not be possible for at least 3 to 5 days or if no clear time frame can be determined for the establishment of enteral feeding. Although a short course (5 days or less) of PN may be used, the quantity of nutrients supplied during the process of initiation and gradual increase to full requirements is so low that it may be difficult to justify. Peripheral PN using fat emulsion as a significant source of calories, however, can provide up to 70 kcal/kg and, with appropriate types and amounts of protein, result in modest weight gain and nitrogen equilibrium.

GASTROINTESTINAL ANOMALIES

Infants with GI anomalies often require PN because the implementation of enteral feedings may be delayed. For example, GI tract atresia or stenosis can obstruct, or partially obstruct, the lumen of the GI tract. This prevents or slows the passage of fluids and nutrients and can result in vomiting, depending on the location of the obstruction. Similarly, infants with necrotizing enterocolitis have zones of ischemic bowel and are at risk for bowel perforation if fed

enterally.[28] Infants with these disorders need PN until the viability of the entire GI tract can be assured.

CHRONIC RENAL FAILURE AND HEPATIC DISEASE

Chronic renal or hepatic disease requires modification of a normal diet to account for the impaired elimination of nitrogenous waste or impaired protein metabolism. Careful caloric supplementation with a reduced amount of protein may permit normal growth while minimizing excess urea production in an infant with renal failure.

CASE 103-6, QUESTION 4: Approximately 48 hours after discharge from the hospital, T.C. returns to the emergency department with abdominal distension and bloody diarrhea. He is diagnosed with postgastroenteritis syndrome. T.C. cannot receive nutrients enterally, and PN is to be initiated because he is nutritionally depleted. Describe for the members of the medical team how a regimen of PN should be initiated for T.C. What aspects of his disease may alter specific nutrient needs?

When initiating PN, the protein (amino acids), glucose (dextrose), fat (lipids or fat emulsion), fluid, and electrolyte, mineral, and vitamin components of the regimen are managed as separate entities. In addition, the route of PN delivery is important to consider because the amount of glucose, potassium, and calcium must be limited if the infusion is given peripherally. In general, 12.5% dextrose, 40 mEq/L potassium, and 10 mEq/L calcium are the maximal amounts that should be provided by infusion into a peripheral vein. These nutrients can be increased if a central venous catheter is placed. The fluids, electrolytes, minerals, and vitamins are initiated at full daily maintenance doses after correction of any preexisting abnormalities. Protein should be initiated at full daily doses in term infants and children with normal renal and hepatic function. Glucose and fat are started at lower doses and increased daily as tolerated until requirements are reached.

Protein should be started in T.C. at full daily requirements of 2 to 3 g/kg/day. Azotemia and acidosis have occurred in infants receiving more than 4 g/kg/day of protein; however, these complications are

rare at the recommended dosage. Parenteral glucose administration is initiated at 5 to 8 mg/kg/minute (7.2–11.5 g/kg/day). At normal maintenance fluid rates, 10% dextrose represents a generally well-tolerated starting solution for patients of virtually any age or size, except the VLBW infant. In T.C.'s case, the dextrose concentration will begin and continue at 10% because of the peripheral catheter limitations. This concentration will provide a glucose infusion rate (GIR) of 7.3 mg/kg/minute. If a central catheter later becomes necessary, the GIR can be increased by 1 to 2 mg/kg/minute each day until the caloric requirement is met. This increase should be accompanied by blood and urine glucose monitoring. If the blood glucose is 150 mg/dL or greater, or if the urine glucose exceeds "trace" amounts, the PN infusion rate should be decreased by at least 25% and a second IV solution should be added to provide needed fluids and electrolytes. Alternatively, the dextrose concentration can be decreased or insulin can be infused concomitantly and titrated to a desired serum glucose concentration of 120 to 140 mg/dL.

Fat emulsion should be initiated at 1 g/kg/day and increased daily by 0.5 to 1 g/kg/day until the maximal dosage of 3 g/kg/day is reached. The daily lipid dose should be infused at a constant rate because fats are better tolerated when infused over 24 hours.[29] Serum triglycerides should be monitored every other day while the dose of fat is being increased. Patients with a fasting triglyceride concentration of 150 mg/dL or less may have their fat dose increased. In patients who are receiving inadequate calories, triglycerides may be elevated because endogenous fats are being mobilized. If the triglyceride concentration is >150 mg/dL, the serum sample must be examined visually. A clear sample with a mildly elevated triglyceride concentration probably indicates the use of endogenous fat stores for energy. Conversely, a turbid or lipemic sample indicates the patient's inability to use the amount of IV fat administered. In this case, further increases in the fat dose should be delayed until triglyceride concentrations decrease.

Special Considerations and Complications

CASE 103-7

QUESTION 1: J.H., a 4-day-old male, was born at 31 weeks' gestation. His birthweight was 4.31 pounds (1.95 kg), and he now weighs 4.51 pounds (2.05 kg). On the first day of life, he was given a commercial preterm infant formula by orogastric tube in gradually increasing quantity with supplemental IV fluids. Now, on the fourth day of life, he has a distended abdomen, and his stools contain bright red blood. An abdominal radiograph shows pneumatosis intestinalis (gas within the intestinal wall seen on x-ray). All enteral feedings are stopped.

What do these findings represent? What are the implications for J.H.'s nutritional management?

Abdominal distension, bloody stools, and pneumatosis intestinalis are characteristics of necrotizing enterocolitis.[30] The causes of this disorder are unclear, but it occurs more often in premature than in term infants; it can occur in clusters of cases, rarely is seen before enteral feeding is instituted, and can be associated with rapid increases in enteral intake.[31] Because J.H. will receive antibiotics for 10 to 14 days and remain NPO, he requires PN. The planned duration of the regimen makes central venous access a necessity.

GOALS OF LONG-TERM SUPPORT

CASE 103-7, QUESTION 2: The following day, intestinal perforation requires the resection of two-thirds of J.H.'s distal jejunum and one-third of his ileum, with the creation of a jejunostomy. The ileocecal valve and the entire colon are left intact. During the operation, a central venous catheter is placed. What is the goal of PN for J.H.?

J.H. will be NPO for a prolonged time. Therefore, the goals of his PN must be to promote normal growth as well as healing of his diseased gut and surgical wounds. Because of J.H.'s prematurity, it will be difficult to predict how well he will tolerate PN. VLBW infants tolerate normal doses of pediatric amino acids without difficulty;

however, some clinicians initiate protein at a lower daily dose (eg, 1 g/kg/day) and advance each day until a goal of 3 to 4 g/kg/day is achieved. Fat should be started at 0.5 to 1 g/kg/day and increased by 0.5 g/kg/day up to 3 g/kg/day. Glucose should be initiated at 6 to 8 mg/kg/minute (5–10 g/kg/day) and increased by 1 to 2 mg/kg/minute (2–3 g/kg/day) until the desired caloric intake is achieved. Appropriate doses of electrolytes and minerals may be started immediately using the guidelines listed in Table 103-1.

FAT EMULSIONS: COMPLICATIONS

CASE 103-7, QUESTION 3: What must be considered in making decisions regarding fat administration in J.H.?

Although J.H. can receive adequate calories using only glucose and crystalline amino acids, he will require fat to provide a more physiologic diet and to prevent essential fatty acid deficiency (EFAD), which develops quickly in low-birthweight infants who have little fat reserve. J.H. should receive a minimum of 5% of his total caloric requirement as fat emulsion or (0.5 g/kg/24 hours) to minimize the risk of EFAD. Ideally, his nutrition regimen will provide ~40% of calories from fat, which is similar to what is provided by human milk.

Infusions of fat emulsion have been associated with impaired oxygen transport and pulmonary ventilation–perfusion mismatch. This adverse effect occurs more often when the dose of fat is 4 g/kg or greater and is infused for a relatively short (4 hours) period. Current practice is to increase the doses of fat gradually from 0.5 to 1 g/kg/day up to a maximum of 3 g/kg/day and to infuse the fat emulsion over the course of 24 hours to minimize the likelihood of pulmonary problems and to promote clearance.

It is unclear whether IV fat administration is detrimental to patients with sepsis. Infusion of fat emulsion has resulted in lymphocyte and neutrophil death.[32] On the other hand, the linoleic acid in IV fat is the precursor to arachidonic acid, prostaglandins, thromboxane,

interleukins, and immune-mediating cells. Theoretically, this may minimize bacteremia. Necrotizing enterocolitis, intestinal perforation, and surgery predispose J.H. to sepsis. Therefore, he should have his IV fat infused at an appropriate dose over the course of 24 hours. Because fat clearance can be impaired during infection, it is also prudent to monitor his triglyceride concentrations.

Free fatty acids can displace bilirubin from its albumin binding sites, thereby placing the infant at risk for kernicterus.[33] Therefore, before advancing the fat dose, the total bilirubin and direct bilirubin should be measured. Patients with an indirect bilirubin (total bilirubin minus direct bilirubin) of 10 mg/dL or less whose albumin levels are normal are at low risk for kernicterus. Indirect bilirubin usually peaks before age 1 week. After the risk for indirect hyperbilirubinemia has passed, the fat dose can be increased as recommended in Table 103-1. The infusion of 1 g/kg over the course of 24 hours is associated with minimal risk for decreased bilirubin binding[33]; however, rapid infusion of this same dose can displace bilirubin from albumin binding sites. Given the low level of indirect bilirubin found on routine monitoring and the planned fat infusion rate, J.H. should not be at risk for kernicterus.

Egg-yolk phospholipids are used to emulsify fats; therefore, patients with a known allergy to eggs (eg, fever, chills, urticaria, dyspnea, bronchospasm, chest pain) should not receive fat emulsion.

GLUCOSE INTOLERANCE

Case 103-7, Question 4: Because J.H. is a premature infant, PN is initiated using 5% glucose, 3 g/kg/day of amino acids, and 0.5 g/kg/day of fat emulsion. The volume of PN should be 240 mL based on a maintenance fluid requirement of 120 mL/kg (see Table 103-1). On the second day, he receives 10% glucose (GIR 8.3 mg/kg/minute), 3 g/kg/day of amino acids, and 1 g/kg/day of fat. On the third day, glucose is increased to 12.5% (GIR 10.4 mg/kg/minute), amino acids remain at 3 g/kg/day, and fat emulsion is increased to 1.5 g/kg/day. On the fourth day, glucose is increased to 17.5% (GIR 14.6 mg/kg/minute), amino acids remain at 3 g/kg/day, and fats are increased to 2 g/kg/day. After this solution has been infused for 8 hours, his urine test yields 1% for glucose (normal, no

glucose), and his blood glucose level is 210 mg/dL (normal, 120 mg/dL). Explain this new finding and the problems it may cause. How should hyperglycemia be managed?

Maximal glucose oxidation rates (mg/kg/minute) are inversely related to age and decrease from 15 to 18 mg/kg/minute in neonates and young infants to 4 to 5 mg/kg/minute in adults. In full-term neonates and infants receiving maintenance fluids (100 mL/kg/day), glucose concentrations can be started at 10 g/kg/day (equivalent to dextrose 10%) and advanced by 2.5 g/kg (equivalent to dextrose 2.5%) every 24 hours up to ~25 g/kg/day (equivalent to dextrose 25%). In preterm neonates, such as J.H., dextrose is started at a lower dose and advanced at smaller increments, usually 2 to 3 g/kg/day. Glucose tolerance varies significantly, so each patient should be considered individually.

At J.H.'s prescribed fluid rate of 10 mL/hour, 17.5% glucose represents 14.6 mg/kg/minute of glucose. The hyperglycemia and glycosuria probably have occurred because the increases in the infusion rate have exceeded J.H.'s ability to adapt to the glucose dose. Patients who have been euglycemic on their glucose dose and then become glucose intolerant should be evaluated, however, for other causes, such as infection and the addition of exogenous corticosteroids. Hyperglycemia and glycosuria can result in serum hyperosmolarity, osmotic diuresis, and dehydration. Regardless of the cause, hyperglycemia should be treated by reducing the glucose administration rate. The rate of the PN infusion can be decreased further if hyperglycemia continues or increased if the hyperglycemia resolves.

When the PN order is written for the subsequent days, the glucose increases should be made in smaller amounts up to the full daily maintenance calorie requirements. Frequent blood and urine glucose monitoring must be continued. Severe glucose intolerance in patients who require PN can be managed with insulin to normalize serum glucose. Although insulin is compatible with PN solutions, it does adsorb to glass, polyvinyl chloride, and filters, resulting in decreased delivery of insulin.[34] Frequently, pediatric patients have

changing insulin requirements that prevent the addition of insulin to PN solutions. A separate continuous infusion of regular insulin (initial dose, 0.05–0.1 units/kg/hour) titrated to control serum glucose concentrations offers a practical solution to minimize waste of the PN solution.[35] It is essential to discontinue the insulin infusion if the PN solution is discontinued to avoid hypoglycemia.

EFFECTS OF BRONCHOPULMONARY DYSPLASIA AND MECHANICAL VENTILATION

CASE 103-7, QUESTION 5: J.H. remains dependent on a ventilator because of his immature lungs. How could J.H.'s respiratory disease influence his nutritional regimen?

After age 28 days, J.H.'s ventilator dependence defines him as having bronchopulmonary dysplasia (BPD), a chronic lung disease of infancy. Historically, BPD is characterized by an increase in resting energy expenditure, increased work of breathing, and growth failure.[36,37] Therefore, J.H.'s caloric requirement may be higher than expected. Additionally, J.H.'s ventilator may also alter the approach to his caloric supply. Very high carbohydrate loads have been associated with an increase in carbon dioxide production.[38] This, in turn, may make it difficult to wean J.H. from the mechanical ventilator. As discussed, rapid infusions of fat emulsion can also have a detrimental effect on pulmonary function. Fat emulsion should not be omitted from J.H.'s PN regimen; rather, a slower infusion rate, with gradual dose increases, while monitoring pulmonary function is appropriate.

PEDIATRIC AMINO ACID FORMULATIONS

CASE 103-7, QUESTION 6: Why would a specialized pediatric amino acid solution be preferable to a standard adult formulation for J.H.?

Patients 1 year of age or older tolerate standard adult amino acid preparations (eg, Aminosyn and Travasol) well. For infants, three specifically designed pediatric amino acid formulations (PAAFs)—TrophAmine, Aminosyn PF, and Premasol—are available. PAAFs were developed in response to the abnormal plasma amino acid patterns noted in infants receiving adult amino acid formulations. The products were designed with the goal of producing plasma amino acid patterns closely matching those of 2-hour postprandial, human milk–fed infants. Theoretically, normal plasma amino acid patterns will promote normal protein synthesis in growing infants.

PAAFs differ from conventional amino acid formulations in several ways. First, they contain a higher content of branched-chain amino acids (leucine, isoleucine, and valine) and a lower content of glycine, methionine, and phenylalanine. In addition, PAAFs have a higher percentage of essential amino acids with a wider distribution of the nonessential amino acids. Finally, PAAFs are unique in that they contain three essential amino acids for neonates: taurine, tyrosine (as *N*-acetyl-L-tyrosine), and cysteine (added as L-cysteine HCl). Adult solutions contain little if any of these amino acids. Neonates have immature liver functions, which results in decreased levels of both hepatic cystathionase and phenylalanine hydroxylase enzymes. Without these enzymes, neonates cannot adequately convert methionine to cysteine or phenylalanine to tyrosine or synthesize taurine from cysteine. Deficiencies in these amino acids can have a significant impact on the health of the neonate. For example, taurine has a role in retinal development, protection and stabilization of cell membranes, neurotransmission, regulation of cell volume, and bile acid conjugation. Taurine also may be important in decreasing or preventing cholestasis associated with long-term PN.

Several investigators have studied the clinical, nutritional, and biochemical effects of TrophAmine in term and preterm infants.[39,40] The use of TrophAmine was found to result in nearly normal amino acid patterns. In addition, patients receiving TrophAmine had greater weight gain and significantly better nitrogen utilization than similar groups using the adult formulations. TrophAmine and Aminosyn PF,

given for a 7-day period, produced comparable weight gain and nitrogen retention.[41] In one study, some of the VLBW infants experienced metabolic acidosis.[39] L-Cysteine, an HCl salt, provides an additional 5.7 mEq of chloride/100 mg and may have contributed to the acidosis. The manufacturer's recommended dose of 40 mg of L-cysteine per gram of amino acid may be too much for the VLBW infant; however, the most appropriate dose has not been determined in these patients.

To date, PAAFs have been effective in producing a positive weight gain and positive nitrogen balance and normalizing amino acid patterns in preterm neonates. They also allow for the provision of larger doses of calcium and phosphorus because PAAFs lower the pH of the final PN solution, providing greater solubility of calcium and phosphorus. Providing appropriate calcium and phosphorus to premature neonates in appropriate ratios is essential to minimize metabolic bone disease. Further evaluation of these products is needed to determine the magnitude of the proposed benefits (ie, improved nitrogen retention, better weight gain, enhanced bone growth, and decreased cholestasis) and the most appropriate L-cysteine dose to use in VLBW infants. In any event, these potential benefits, and clinical experience with these products, have resulted in the use of PAAFs as the standard of care in infants requiring PN.

CARNITINE

Case 103-7, Question 7: Why would carnitine supplementation be warranted in J.H.?

Carnitine has many functions within the body, but it primarily serves to transport long-chain fatty acids (LCFAs) across the mitochondrial membrane where they undergo β-oxidation to produce energy. Deficiency in carnitine lessens LCFA availability for oxidation, resulting in the accumulation of LCFA and a decrease in ketone and adenosine triphosphate (ATP) production. This can adversely affect the CNS and skeletal and cardiac muscles.

Carnitine deficiency in premature infants also has been linked to disorders such as GI reflux, apnea, and bradycardia.[42]

Whereas carnitine is a nonessential nutrient in adults and is readily available from a diet that includes meat and dairy products, it appears to be an essential nutrient in neonates and infants. This population has low body stores of carnitine and a decreased ability to synthesize it on their own. The premature infant has even lower stores because carnitine accumulation occurs during the third trimester. Human milk and most cow's milk–based infant formulas contain carnitine. Some soy-based formulas have additional carnitine added during manufacturing. PAAFs, however, are not routinely supplemented with carnitine. Therefore, infants who are exclusively fed by PN that is not supplemented with carnitine are at risk for developing complications associated with carnitine deficiency.[42]

J.H. has two risk factors for the development of carnitine deficiency (prematurity and exclusive use of PN), and because carnitine has little or no adverse effects associated with its use, it would be appropriate to provide J.H. with a carnitine supplement. Carnitine is available as both an oral and IV formulation. The recommended dose in J.H. is 10 to 20 mg/kg/day. The addition of carnitine directly to PN improves carnitine plasma concentrations and nutritional status.

METABOLIC BONE DISEASE (RICKETS)

CASE 103-7, QUESTION 8: On the chest radiograph taken to evaluate the concern for sepsis, the radiologist notes that J.H. has two rib fractures and that the bones appear undermineralized. The most recent laboratory values show a serum calcium (Ca) of 9.3 mg/dL (normal, 8.5–10.5 mg/dL), a serum phosphorus of 3.6 mg/dL (normal, 4.0–8.5 mg/dL), and an alkaline phosphatase of 674 units/L (normal, 350 units/L). What diagnosis is suggested by these findings? How and why has J.H.'s nutrition regimen placed him at risk for this disease?

During the last trimester of pregnancy, bone accretion is accelerated, reaching its peak at about 36 weeks. Premature infants,

therefore, require larger calcium and phosphorus doses. Limitations to venous access, however, may preclude the infusion of concentrated calcium solutions peripherally, and the patient's end organs may be resistant to vitamin D. Thus, metabolic bone disease is not unexpected in a premature infant such as J.H.

Aluminum, a contaminant in some parenteral salt products (particularly calcium), also may play a role in impaired bone mineralization.[43] Low serum phosphorus with high alkaline phosphatase, undermineralized bones, and fractures resulting from routine handling are consistent with a diagnosis of rickets.

PN solutions provide calcium and phosphorus in much smaller amounts than the infant would accumulate in utero.[44] Solution pH, temperature, calcium salt, and final calcium and phosphorus concentrations influence their solubility in PN solutions. An acidic PN solution favors the solubility of these salts. The pH of commercially available amino acid preparations ranges from 5.4 in PAAFs to 7 in adult amino acid formulations. The addition of L-cysteine, with a pH of 1.5, also makes the solution more acidic. Because of the added acidity of dextrose, solutions with higher dextrose concentrations are more acidic. Of note, colder storage temperatures promote calcium and phosphorus solubility. Therefore, refrigerated PN solutions may appear to be free of precipitate on visual inspection. Calcium and phosphate can precipitate, however, when warmed to room temperature or when infused into patients with fever or in incubators. Calcium salt selection is another important consideration because the chloride salt dissociates rapidly and favors precipitation, whereas the gluconate and gluceptate salts dissociate less quickly.

Serum phosphorus concentrations should be monitored several times per week and phosphorus intake adjusted to prevent symptomatic hypophosphatemia. Serum calcium is not useful as an indicator of disease activity because it will remain normal at the expense of bone mineralization. This is demonstrated by J.H.'s serum calcium at the time of diagnosis.

Parenteral Nutrition–Associated Liver Disease

CASE 103-7, QUESTION 9: On the 56th day of life, J.H. is noted to be mildly jaundiced. A review of his laboratory tests reveals the following:

	Age (days)				
Test	22	29	36	43	50
Aspartate aminotransferase (AST) (units/L) (normal, >40)	14	17	15	20	25
Alanine aminotransferase (ALT) (units/L) (normal, >28)	6	7	10	10	11
Alkaline phosphatase (international units/L) (normal, >350)	103	158	345	506	695
Bilirubin					
Indirect (normal, >1 mg/dL)	0.9	0.9	0.8	0.8	0.9
Direct (normal, >0.2 mg/dL)	0.1	0.1	0.8	1.6	3

Could this be related to his PN?

Parenteral nutrition–associated liver disease (PNALD) is a severe liver disease because of extended parenteral feeding, which can cause permanent damage and even liver failure. In past decades, hepatic damage has been reported in up to one-half of infants receiving PN,[45] with a higher prevalence (up to 50%) in VLBW infants such as J.H. Although it is still a concern today, PNALD is less prevalent because of a better understanding of how to treat infants requiring long-term PN. The laboratory abnormalities reported in J.H. are typical of this complication. The first change observed is

usually an elevated direct (conjugated) bilirubin, which can occur as early as 2 weeks after beginning PN. Increases in the serum concentrations of the hepatic enzymes, aspartate aminotransferase (AST) and alanine aminotransferase (ALT), lag 2 weeks or more behind the rise in direct bilirubin. Alkaline phosphatase also can rise, but it is a nonspecific indicator of liver disease. Alkaline phosphatase is produced by the liver, GI tract, and bones. Although the laboratory results observed in J.H. are consistent with the pattern associated with PNALD, and many components of PN solutions have been associated with the development of cholestasis, other potential causes also exist.[45] PNALD is a diagnosis of exclusion; therefore, other causes, such as viral hepatitis, must be ruled out.

J.H. has several other risk factors for developing cholestasis, and prolonged enteral fasting may be the most significant.[45] Stimulation of bile flow and gallbladder contraction depend on GI hormones, which depend on enteral feeding for their release.[45] Absence of these hormones, therefore, can promote cholestasis.[45] Immature hepatic function secondary to prematurity also places J.H. at risk, in addition to the duration of PN therapy. As the duration of PN use increases, so does the prevalence of hepatic disease in premature infants; 25% of infants nourished in this manner for 30 days or more show evidence of cholestasis.[45] Surgical patients have a greater likelihood of developing hyperbilirubinemia than medical patients, especially those requiring GI surgery.[45] Many surgical procedures are associated with a higher risk of jaundice.[45] Finally, J.H.'s infection increases his risk for cholestasis.[45]

In addition to the overall duration of PN, specific components within PN have been linked to liver injury. Lipid emulsions can have a direct effect on hepatocytes causing inflammation within the liver. Fat preparations high in omega-6 fatty acids and phytosterols are thought to lead to an accumulation, ultimately decreasing bile flow. The use of adult amino acid preparations in infants can also increase the risk of cholestasis. In one study, the incidence of cholestasis in VLBW infants receiving TrophAmine was reduced to 23% relative to historical controls of 30% to 50%.[46] In another study comparing TrophAmine and Aminosyn PF, 33% of infants receiving Aminosyn

PF developed cholestasis as compared with 13% of infants who received TrophAmine.[47] An additional risk factor for cholestasis not present in J.H. is the administration of large amounts of protein or dextrose. Because amino acids are actively transported in hepatocytes, it is important to provide appropriate types and amounts of amino acids to minimize the development of cholestasis. In one study, a high-protein regimen (3.6 g/kg/day) was associated with an earlier onset and greater degree of cholestasis than a low-protein regimen (2.3 g/kg/day).[48] Similarly, dextrose overload is also a known cause of hepatic steatosis. Therefore, overly aggressive feeding of J.H. with PN should be avoided.

Along with hepatic damage, gallstones have been reported in infants and children receiving PN.[45] The ileal resection performed during the acute phase of his necrotizing enterocolitis may put J.H. at increased risk for this hepatobiliary complication as well.

Case 103-7, Question 10: What modifications to J.H.'s PN regimen should be made in the presence of cholestasis?

First, the institution of enteral feeding must be considered. Even low-volume trophic feeding may help alleviate the condition and should be attempted in patients with cholestatis. Next, the protein and glucose dose provided by the PN should be evaluated. During cholestasis, calories should be provided using an appropriate mix of protein, carbohydrate, and fat.
